While new phenomena have been discovered and explored, there are still fundamental questions as to the nature of the spin-transfer interaction. The form of the interaction and its dependence on layer composition and structure is only beginning to be understood quantitatively. The magnetization dynamics excited by the spin-transfer interaction is also poorly understood. For example, the spatial structure of the modes excited and the relaxation and switching pathways are unknown. Improved modeling, nanomagnet, and material structures as well as more detailed transport and magnetic characterization should lead to a better understanding of the physics of spin transfer.

ACKNOWLEDGMENTS

I would like to particularly acknowledge Barbaros Özyilmaz, whose thesis research formed the basis for this article. There were also very important contributions from Jonathan Sun and Wenyu Chen. I would also like to thank P. M. Levy, M. Stiles, and A. Brataas for many insights and useful discussions of this work. This research was supported by grants from NSF-DMR-0405620, DMR-0706322 and by ONR N0014-02-1-0995.

1 INTRODUCTION: SPIN-TRANSFER EFFECTS IN NANOMAGNETS

Present applications of thin-film giant magnetoresistance (GMR) spin valves (Dieny, 1994) and magnetic tunnel junctions (Moodera, Nassar and Mathon, 1999) include read-back heads for magnetic information storage in hard drives (Wang and Taratorin, 1999), storage bits in magnetoresistive random access memory (MRAM) (Åkerman *et al*., 2004; Debrosse *et al*., 2004), and magnetic sensors for biological, robotic, and automotive systems (Daughton, 2003; Freitas *et al*., 2004). For such devices, the relative alignment of the individual magnetic moments, and thus also the magnetoresistive signal, is manipulated by a magnetic field. Spin transfer, first predicted by Slonczewski (1996) and Berger (1996), offers a new way to control the magnetic alignment in nanostructured devices using applied electric current instead of magnetic field. When a current flows through a trilayer of two ferromagnets separated by a nonmagnetic spacer, the electrons acquire a spin polarization after passing through the first, or fixed, ferromagnet. As the spin-polarized electrons are incident on the second, or free, ferromagnet, the transfer of spin angular momentum produces a torque on the free magnetization. Magnetic excitations observed as a result of the spin transfer include both a hysteretic reversal (Myers *et al*., 1999; Wegrowe *et al*., 1999; Katine *et al*., 2000; Grollier *et al*., 2001; Mancoff and Russek, 2002; Sun *et al*., 2002; Mancoff *et al*., 2003) or sustained high-frequency precession (Tsoi *et al*., 2000; Kiselev *et al*., 2003; Rippard *et al*., 2004a; Covington *et al*., 2004; Kiselev *et al*., 2004; Rippard *et al*., 2004b) of the magnetization.

The dynamics of the free layer's magnetic moment under a spin-polarized applied current I_{dc} can be described using the Landau–Lifshitz–Gilbert equation with the inclusion of the spin-transfer torque (Slonczewski, 1996):

$$\frac{\mathrm{d}\vec{m}}{\mathrm{d}t} = -\mu_0\gamma\vec{m}\times\vec{H}_{\mathrm{eff}} - \mu_0\gamma\alpha\vec{m}\times(\vec{m}\times\vec{H}_{\mathrm{eff}}) + \frac{\varepsilon I_{\mathrm{dc}}\hbar\gamma}{2eMAt}\vec{m}\times(\vec{m}\times\vec{p}) \quad (1)$$

where $\vec{m}$ and $\vec{p}$ are the free and fixed layer magnetization directions, γ is the gyromagnetic ratio, $\vec{H}_{\mathrm{eff}}$ is the effective

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

magnetic field including the applied and demagnetizing fields, α is the damping parameter, μ_0 is the permeability of free space, ε is the spin-transfer efficiency, $\hbar$ is Planck's constant, e is the electron charge, M is the free layer saturation magnetization, A is the particle area, and t is the layer thickness. The first term on the right describes the usual precession of $\vec{m}$ about $\vec{H}_{\text{eff}}$. The second term on the right gives the magnetic damping, which tends to drive $\vec{m}$ toward $\vec{H}_{\text{eff}}$. The spin-transfer torque is given by the final term on the right, which is proportional to I_{dc}. For the correct sign of I_{dc}, the spin-transfer torque opposes the magnetic damping term and possibly cancels it out completely. In this case, spin transfer will produce either a hysteretic switch or a steady-state coherent oscillation of $\vec{m}$ depending on the relative strength of I_{dc} and the applied magnetic fields and anisotropies (Slonczewski, 1996, 1999). In this single-domain model, the spin-transfer dynamics depend on the current density I_{dc}/A and would be identical for devices with different diameters when driven with the same current density. The single-domain model, however, ignores effects due to current-generated oersted fields, nonuniform magnetization, and associated exchange energies.

Spin transfer generally becomes significant for nanosized ferromagnets, in which the reduced device dimension d allows the large critical current densities of $10^{10}-10^{11}\,\text{A m}^{-2}$ required for large spin-transfer effects. The spin-transfer torque is proportional to the current density and so varies as d^{-2}. The oersted magnetic field from the current flow also acts on the magnetic moment and varies as d^{-1}. Thus, spin transfer dominates at small d (Slonczewski, 1996). Experimental observations of spin-transfer effects have been reported for $d < 30-200\,\text{nm}$ and include systems such as patterned magnetic nanopillars (Katine *et al*., 2000; Grollier *et al*., 2001; Mancoff and Russek, 2002; Sun *et al*., 2002; Kiselev *et al*., 2003; Mancoff *et al*., 2003; Kiselev *et al*., 2004; Covington *et al*., 2004), mechanical point contacts (Tsoi *et al*., 2000; Rippard, Pufall and Silva, 2003; Ji, Chien and Stiles, 2003; Pufall, Rippard and Silva, 2003), lithographic point contacts (Myers *et al*., 1999; Rippard *et al*., 2004a,b), magnetic tunnel junctions (Huai *et al*., 2004; Fuchs *et al*., 2004), and magnetic nanowires (Wegrowe *et al*., 1999). The possibility for electrical control of magnetization through an applied current, as well as the increasing importance of spin transfer at reduced device sizes, makes spin transfer relevant for nanoscale device applications. Spin-transfer-induced hysteretic magnetic switching could allow a low-power, high-density MRAM written by applied current, rather than applied magnetic field. Also, the microwave output power from the spin-transfer high-frequency magnetic precession state can form the basis for a frequency-tunable, current-controlled nanoscale oscillator. Potential spin-transfer applications are discussed later.

In this article, we discuss spin-transfer-induced high-frequency precession, focusing on experiments at both Freescale Semiconductor and the National Institute of Standards and Technology (NIST) on GMR point contacts. We describe two issues of importance both for fundamental understanding as well as for potential applications: the dependence of spin-transfer precession properties on the area of a single point contact, as well as the observation of phase locking between separate spin-transfer oscillators. First, with regard to the area dependence, we discuss measurements at Freescale of spin-transfer resonance in contacts with diameter d ranging from less than 50 nm to almost 300 nm (Mancoff, Rizzo, Engel and Tehrani, 2006). The resonance frequency f increased nearly linearly with I_{dc}, but the decreasing dependence of the slope $\text{d}f/\text{d}I_{\text{dc}}$ on d deviated from a simple d^{-2} form given by the current density. Instead, the data was fit by an empirical model in which the large-angle precession region extends beyond the contact diameter by a ring of width $\delta \approx 50\,\text{nm}$. Also, the increase of the spin-transfer precession critical current I_{c} with contact area could be fit equivalently well by the model including the ring δ or by previous theory (Slonczewski, 1999).

Next, with regard to phase locking between spin-transfer oscillators, we examined devices with two separate point contacts to a single GMR spin valve film. The Freescale group measured the dependence of spin-transfer phase locking on the intercontact spacing (Mancoff, Rizzo, Engel and Tehrani, 2005). For two 80-nm diameter contacts electrically connected in parallel to a single top electrode, we observed an onset of phase locking between the two resonances for center-to-center spacings less than around 200 nm. The NIST group investigated devices with two contacts spaced by 500 nm and with separate electrical connections (Kaka *et al*., 2005). The current bias of one contact was varied to tune its resonance frequency toward that of the second contact with constant current bias. Over a range in current bias, the precession of both contacts phase locked. For both the Freescale and NIST data, the phase-locked resonance possessed an increased output power and a decreased linewidth due to coherence between the oscillators.

2 EXPERIMENTAL DETAILS

Figure 1(a) shows a typical cross section of a metallic point contact through a thick insulator to a GMR spin valve. The GMR film was patterned with lateral dimensions greater than 8 μm, so any edge defects were far from the point contact. The GMR film was insulated either by a cross-linked PMMA electron-beam (e-beam) lithography resist or SiO_2. The use of SiO_2 has some advantages, including more compatibility with industrial fabrication of spintronics

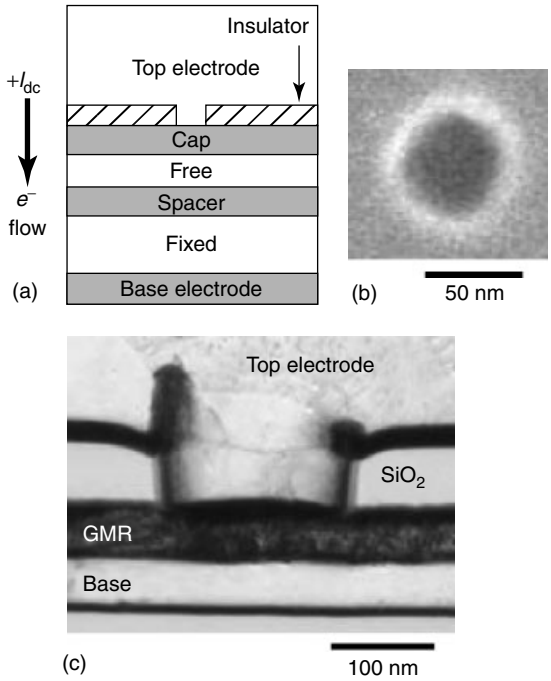

Figure 1. (a) Cross section of a via through an insulator to a GMR film. (b) Plan-view SEM image of a nominal 60-nm diameter contact. (c) Cross-section TEM image of a point contact to a GMR film. devices such as MRAM, allowing optical lithography to pattern the contact via, and avoiding the time-consuming high-dose e-beam exposure needed to cross-link the PMMA. The nominal lithographic contact diameter ranged from less than 50 nm up to 300 nm. Figure 1(b) is a plan-view scanning electron microscope (SEM) image of a nominally 60-nm contact written by e-beam lithography and etched through SiO_2. Figure 1(c) is a cross-section transmission electron microscope (TEM) image of a nominally 160-nm optical lithography contact, also using a SiO_2 insulator.

The GMR film typically consisted of a nonmagnetic base electrode, a relatively thick ferromagnetic fixed layer, a nonmagnetic Cu spacer layer, a relatively thin ferromagnetic free layer, and a nonmagnetic cap. Figure 2(a) shows a measurement at low current bias of the current-perpendicular-to-plane (CPP) GMR in a nominally 50-nm diameter contact. The fixed layer was 20-nm $Co_{81}Fe_{19}$, the Cu spacer was 6 nm thick, and the free layer was 4.5-nm $Ni_{80}Fe_{20}$. The CPP GMR switching was determined by the $Ni_{80}Fe_{20}$ and $Co_{81}Fe_{19}$ coercivities.

The high-frequency electrical measurement setup (top-down view in Figure 2b) was similar to that used for other high bandwidth measurements of magnetic devices (Russek and Kaka, 2000; Stutzke, Burkett and Russek, 2003; Kaka and Russek, 2002). The GMR film was patterned into part of the bottom electrode. I_{dc} flowed from a current source into a bias tee and then into the device via a high-frequency microwave probe. A lock-in amplifier measured the device resistance at low frequencies (<kHz). I_{dc} excited spin-transfer precession of the free layer and an associated oscillation of the device resistance through the GMR. The microwave voltage output is the product of I_{dc} and the oscillating resistance. The high-frequency signal passed through the bias tee into a microwave amplifier and then a spectrum analyzer. The amplifier gain was divided out of all data presented. Measurements were at room temperature with $+I_{dc}$ defined as electron flow from the free to the fixed magnetic layer. The chip and probe were mounted on a rotatable stage for which a magnetic field applied to the device could be varied between in plane and out of plane.

3 CONTACT AREA DEPENDENCE OF SPIN-TRANSFER RESONANCE

In this section, we describe measurements at Freescale of spin-transfer resonance in devices with a single GMR point contact, as in Figure 1, focusing on the dependence of the spin-transfer precession as a function of the contact size (Mancoff, Rizzo, Engel and Tehrani, 2006). In recent measurements of high-frequency (5–40 GHz) spin-transfer magnetization precession, the dependence on the lateral device area has not been examined (Kiselev *et al*., 2003,

Rippard *et al*., 2004a; Covington *et al*., 2004; Kiselev *et al*., 2004; Rippard *et al*., 2004b). However, understanding the area dependence is important in determining the details of the spin-transfer-induced dynamics, particularly the precession's spatial extent and lateral coherence, the importance of the oersted field, and the type of magnetic spin-wave excitations generated. The area dependence is also critical for understanding the scaling of spin-transfer devices in applications such as low-power, high-density MRAM or nanoscale current-driven, tunable microwave oscillators.

The measured device contact resistance versus the nominal designed contact diameter d_{nominal} (squares) from 50 to 300 nm is plotted in Figure 3(b). The data are averages for 35 contacts total of varied size. The dashed line is a fit of a Sharvin–Maxwell calculation for the point contact resistance (Wexler, 1966), for which we let the contact area differ from the nominal area by an amount equal to a ring of constant width. This area difference was determined by the fit as a decrease from the nominal diameter by a ring of width ≈8 nm, likely due to a slight loss in pattern fidelity in forming the contact.

For the experiments, the spin valve typically contained a 20-nm $Co_{81}Fe_{19}$ fixed layer, a 6-nm Cu spacer, and a 4.5-nm $Ni_{80}Fe_{20}$ free layer. Figure 3(a) shows the frequency spectrum amplitude measured for a nominally 300-nm diameter contact at I_{dc} from 50 to 75 mA in an applied magnetic field of approximately 1 T normal to the thin-film plane. At this magnetic field, the $Ni_{80}Fe_{20}$ free magnetization was saturated out of plane while the $Co_{81}Fe_{19}$ fixed magnetization pointed ≈30° out of plane, according to Stoner–Wohlfarth calculations. The spin-transfer precession manifested itself as a sharp peak in the frequency spectrum above a critical current at $+I_{\text{dc}}$. The signal resulted from the GMR as the $Ni_{80}Fe_{20}$ free layer magnetization moved while the $Co_{81}Fe_{19}$ magnetization was fixed with respect to spin transfer due to its larger thickness and magnetization compared to the $Ni_{80}Fe_{20}$. The peak precession frequency increased monotonically with I_{dc} (Figure 3(a)). This increasing trend is also demonstrated in Figure 4 as a map of the voltage amplitude which is a function of both the frequency spectrum and I_{dc}. The peak precession frequency increased with I_{dc} at an average rate of around 120 MHz mA^{-1} for this device, demonstrating an electrically controlled resonance frequency that may be of use in a practical oscillator device. The peak precession frequency displays occasional discontinuous jumps at certain values of I_{dc}, such as at around 57 mA and a larger jump at around 73 mA as seen in Figure 4. The origin of these discontinuities is unknown (Rippard *et al*., 2004a,b; Kiselev *et al*., 2004) but may be associated with spin-transfer excitation of the nominally fixed magnetic layer or a change in the mode structure within the free layer.

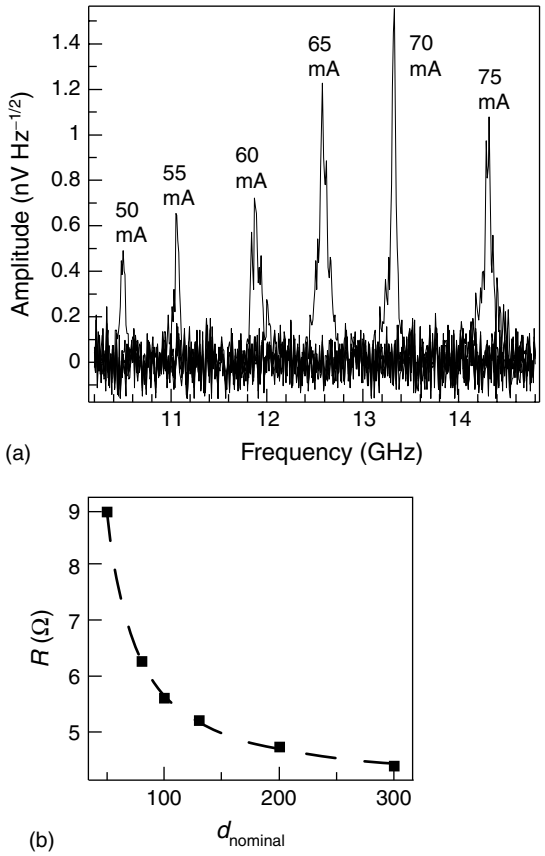

Figure 3. (a) Voltage amplitude versus frequency for a GMR contact of nominal diameter 300 nm. (b) Contact resistance versus nominal diameter d_{nominal} (squares). The dashed line is a Sharvin–Maxwell fit. Error bars in (b) are smaller than the data points. (Reproduced from F.B. Mancoff *et al*., 2006, with permission from the American Institute of Physics. © 2006.)

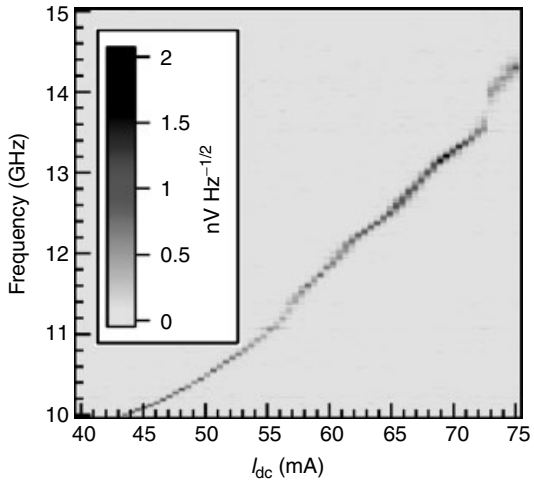

Figure 4. Map of voltage spectrum amplitude versus frequency and current bias I_{dc} for the GMR contact of nominal diameter 300 nm from Figure 3(a).

In this geometry, with the magnetic field applied perpendicular to the film plane, the fixed layer does not have a large Zeeman energy to fix the direction of the layer in the azimuthal direction, and motion of the fixed layer can occur.

Figures 3(a) and 4 demonstrate spin-transfer precession in the largest area devices to date. Such clear spin-transfer precession in larger devices is somewhat surprising since, as described previously, spin transfer competes with the self-generated magnetic field from the current flow and is typically dominant only at small contact diameters (Slonczewski, 1996). Nevertheless, we observed robust spin-transfer resonance in devices as large as almost 300 nm diameter. Although the data in Figures 3(a) and 4 were from a contact formed using e-beam lithography, we also observed similar spin-transfer resonance in contacts patterned with optical lithography (Figure 1c). Optical lithography offers simplified fabrication for applications by avoiding e-beam lithography, which was used for almost all spin-transfer studies so far (See Huai *et al*., 2004 for an exception).

As a function of the physical diameter d_{SM} determined from the Sharvin–Maxwell fit in Figure 3(b), the measured frequency full-width at half-maximum (*FWHM*) was as small as <10 MHz (Figure 5a) and the quality factor *f/FWHM* was as large as >1700 (Figure 5b), both roughly constant with d_{SM} from 35 nm to almost 300 nm. Each data point in Figure 5(a) and (b) is the minimum *FWHM* and maximum *f/FWHM* measured for a given contact over the range of I_{dc} and magnetic fields examined. The solid lines are the average of the data points for a given diameter. The maximum integrated resonance power ranged from around 200 pW at the smaller sizes to 1–5 pW in the largest devices.

The spin-transfer peak precession frequency f versus I_{dc} measured for nominal contact diameters from 50 to 300 nm is shown in Figure 6(a), with the labels giving d_{SM} for each contact. For all sizes, the measured f (crosses) increased approximately linearly with I_{dc} (dotted lines are linear fits). This linear dependence agrees with Landau–Lifshitz–Gilbert calculations using a spin-transfer torque term for a single-domain particle (Slonczewski, 1996; Lee, Redon and Dieny, 2005), and also for the spatially nonuniform case including nonlinearities from both exchange and dipole coupling (Hoefer *et al*., 2005). The physical picture is as follows: normally, the damping torque aligns the $Ni_{80}Fe_{20}$ free moment with the effective magnetic field and produces a non-precessing, zero torque steady state. The spin-transfer torque opposes the magnetic damping torque so the free moment can have a nonzero angle with the field in equilibrium and undergo steady-state precession. Increased I_{dc} and spin-transfer torque drive the $Ni_{80}Fe_{20}$ free layer to larger steady-state precession angles with the 1 T applied magnetic field. Then, the demagnetizing field of the $Ni_{80}Fe_{20}$ is reduced

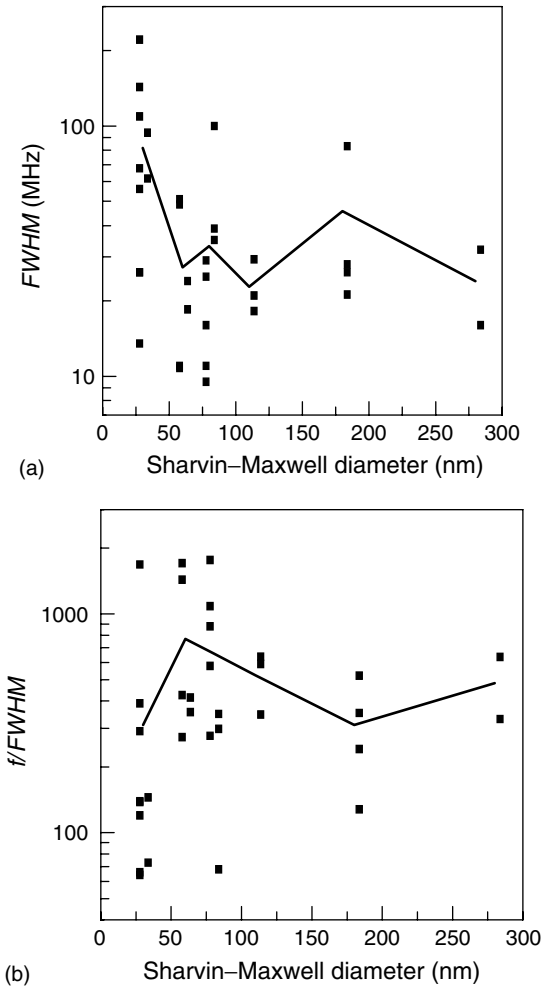

Figure 5. (a) Minimum spin-transfer resonance full-width at half-maximum *FWHM* of the voltage spectrum and (b) maximum resonance quality factor *f/FWHM* versus physical contact diameter d_{SM} from the Sharvin–Maxwell fit in Figure 3(b). Solid lines show the average data points.

and no longer nearly cancels the applied field, so that the net internal field, the magnetic torque, and therefore also the precession frequency f increase.

The slope df/dI_{dc} (squares) versus the contact diameter d_{SM} from the fit to the Sharvin–Maxwell calculation is shown in Figure 6(b). The data are averages of 17 contacts total of varied size. The error bars are the standard error in df/dI_{dc}. The dashed line is a fit of $df/dI_{dc} \propto 1/d^2_{SM}$, which assumes f to be proportional to the current per area defined by the contact diameter d_{SM}. As shown, this fit was quite poor (reduced $\chi^2 \gg 1$). Compared to the dashed fit, the observed slope df/dI_{dc} increases much more slowly with decreasing d_{SM}, which implies that the contacts require more current (or torque) to increase f than expected from the physical contact diameter. This difference is largest for the smallest contacts.

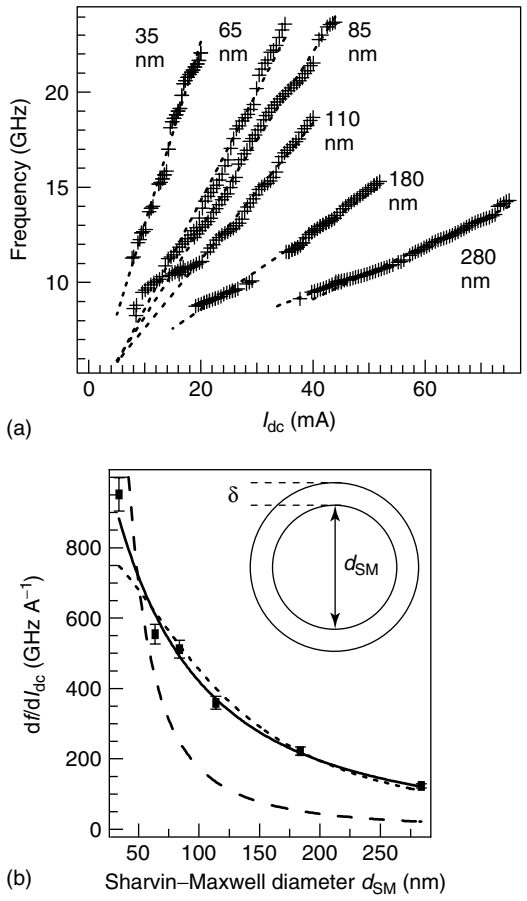

Figure 6. (a) Peak frequency f versus current I_{dc} for varied contact size (labels give the physical diameters d_{SM} from the Sharvin–Maxwell fit in Figure 3b). (b) Slope df/dI_{dc} versus d_{SM}. The solid line fit to $df/dI_{dc} \propto 1/(d_{SM}/2+\delta)^2$ determines $\delta \approx 50$ nm. A similar fit with $\delta = 0$ (dashed line) does not match the data. The dotted fit to $df/dI_{dc} \propto 1/(\pi(d_{SM}/2)^2 + C)$ with a constant area C does not fit the data as well as the solid line. (inset) Top-down view of a GMR contact, showing d_{SM} and δ. (Reproduced from F.B. Mancoff *et al.*, 2006, with permission from the American Institute of Physics. © 2006.)

As a starting model, we hypothesized that the contacts have a larger area of precessing spins than given by $A_{SM} = \pi(d_{SM}/2)^2$, since the strong magnetic exchange coupling must create a finite transition between the coherently precessing spins under the contact and the approximately static spins far outside it. In addition, energy losses due to dipolar radiation and spin-wave generation will increase the effective contact area. Spin-wave radiation losses were previously included in the theory of the critical current I_c for spin-transfer precession in point contacts (Slonczewski, 1999), but as a constant term independent of area.

As a first approximation, we assumed that the strongly precessing region extends into the continuous $Ni_{80}Fe_{20}$ film by a ring of constant width δ around the physical diameter d_{SM} (see a schematic, overhead view of the contact in the inset to Figure 6b). The modified fit of $df/dI_{dc} \propto 1/(d_{SM}/2+\delta)^2$ to the data (solid line in Figure 6b) was good (reduced $\chi^2 \approx 1.8$). The fit determined $\delta \approx 50$ nm, which results from magnetic excitation in the surrounding $Ni_{80}Fe_{20}$ film. This δ value for the excitation length is several times greater than the magnetic exchange length, which is ≈6 nm for the $Ni_{80}Fe_{20}$ film (Hoefer *et al.*, 2005). For interactions between two contacts in close proximity, each with $d_{SM} \approx 65$ nm, for example, this δ value implies that for a center-to-center spacing of $d_{SM} + 2\delta \approx 170$ nm, the precessing regions will interact. This estimate is consistent with our observation (see next section) of phase locking of the spin-transfer resonances for two $d_{SM} \approx 65$ nm contacts at center-to-center spacings <200 nm in the Freescale devices (Mancoff, Rizzo, Engel and Tehrani, 2005).

We also fit the form $df/dI_{dc} \propto 1/(\pi(d_{SM}/2)^2 + C)$ to the data in Figure 6(b) (dotted line), where C is a constant area of magnetic excitation in addition to $\pi(d_{SM}/2)^2$. We were motivated to use this form by a theoretical expression for I_c versus area (see Slonczewski, 1999 and equation (2) in the following text) in which I_c is proportional to the sum of the contact area and a constant term independent of area due to spin-wave radiation to the surrounding film. The fit determined a minimum spin precession area of $C \approx \pi(110\,\text{nm}/2)^2$, but did not match the data nearly as well (reduced $\chi^2 \approx 8.3$) as the solid line fit using the δ-ring model. In addition, as another comparison for the data in Figure 6(b), a decreasing trend for df/dI_{dc} versus contact size has also been recently calculated in the case of a spatially nonuniform precession for the contact (Hoefer *et al.*, 2005).

We used finite element simulations to estimate the increase in precessing area due to current spreading from the current injection site. The injected current density's lateral extent was approximately 3 nm (6 nm) outside the physical contact area in a horizontal plane at the top (bottom) of the 6-nm-thick Cu spacer layer. We thus conclude that current spreading is a relatively minor contribution to the increased magnetically active area given by the ring width $\delta \approx 50$ nm.

We also measured the spin-transfer critical current I_c versus area $A_{SM} = \pi(d_{SM}/2)^2$ for an out-of-plane applied magnetic field of 1 T (Figure 7a). I_c is the lowest current for which the spin-transfer peak in frequency was observed. The data are averages of a total of 17 contacts of varied size, and the error bars show the standard error in I_c. A theoretical form for I_c versus contact area A derived using the spin-transfer torque is (Slonczewski, 1999):

$$I_c = \frac{etM}{\hbar\varepsilon}\left[\frac{23D}{2\hbar\gamma} + 2A\alpha\left(B_{app} - \mu_0 M\right)\right] \qquad (2)$$

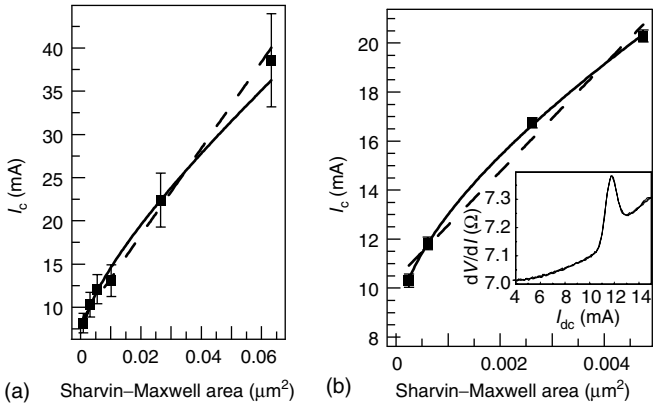

Figure 7. (a) Spin-transfer resonance critical current I_c versus area from the physical contact diameter d_{SM} from the Sharvin–Maxwell fit in Figure 3(b). A 1 T magnetic field was applied out of plane. (b) I_c versus area, with an in-plane field of 40 mT and with I_c measured from peaks in quasistatic dV/dI versus I_{dc} (inset), which correspond to the onset of spin-transfer-induced low frequency noise. The data in the inset is from a nominally 50-nm diameter contact. Dashed lines are fits to equation (2) for (a) or equation (3) for (b), and the solid curves are fits to modified forms including a ring δ in the area calculation. (Reproduced from F.B. Mancoff *et al*., 2006, with permission from the American Institute of Physics. © 2006.)

where e is the electron charge, t is the free layer thickness, M is the magnetization, $\hbar$ is Planck's constant, ε is the spin-transfer efficiency, D is the exchange parameter, γ is the gyromagnetic ratio, α is the damping parameter, B_{app} is the applied magnetic field, and μ_0 is the permeability of free space. The first term on the right in equation (2) represents damping of the spin-transfer torque due to spin-wave radiation losses to the surrounding magnetic film, while the second term in equation (2) results from the conventional magnetic damping. For small contact areas, the spin-wave radiation term dominates the dissipation of the spin-transfer excitation, while the conventional damping term becomes more significant for larger contacts.

The fit of equation (2) is shown in Figure 7(a) (dashed line). Using $t = 4.5\,\text{nm}$, $M \approx 640\,\text{kA m}^{-1}$ from vibrating sample magnetometry, and $D = 3.5\,\text{meV-nm}^2$ (Pufall, Rippard and Silva, 2003) for the $Ni_{80}Fe_{20}$ free layer, we find $\varepsilon \approx 0.18$ and $\alpha \approx 0.07$. This ε is in fair agreement with results by a different technique where $\varepsilon \approx 0.29$–0.56 for $Co_{90}Fe_{10}$/Cu multilayers or $\varepsilon \approx 0.17$–0.38 for $Ni_{80}Fe_{20}$/Cu multilayers (Pufall, Rippard and Silva, 2003). ε is reduced in our devices since the fixed layer magnetization is $\approx 30^\circ$ out of plane instead of 90° as assumed for equation (2). The in-plane magnetization and corresponding spin polarization do not contribute to precession, so ε is reduced, in this case by a factor of $\approx$2, compared to when the fixed layer magnetization is 90° out of plane. The α value is somewhat large compared to that measured for continuous $Ni_{80}Fe_{20}$ films ($\alpha \approx 0.01$) but closer to that measured for large-angle precession in patterned nanostructures ($\alpha \approx 0.03$) (Kaka *et al*., 2003).

We also fit the data to a modified form of equation (2) with $I_c \propto (A_{SM} + \Delta A)$, where ΔA is the extra area of the ring of width δ and the proportionality constant contains the same prefactors as the area term in equation (2). This modified form incorporates the spin-wave radiation loss term using the additional excitation ring δ, instead of the constant term independent of area (first term on the right in equation (2)). The fit to this equation (solid curve in Figure 7a) determined $\delta \approx 90\,\text{nm}$ (comparable to $\delta \approx 50\,\text{nm}$ from Figure 6) as well as $\alpha/\varepsilon \sim 0.16$, which gave $\alpha \approx 0.03$ assuming $\varepsilon \approx 0.18$ as found previously. The quality of the two fits in Figure 7(a) was roughly equal given the data uncertainty, though the fit incorporating the ring δ gave a more reasonable α.

In Figure 7(b), we again plot I_c versus A_{SM}, but now for an in-plane applied magnetic field of 40 mT. The data are averages of more than 80 devices of varied size. Error bars showing the standard error in I_c are smaller than the data points. The I_c values in Figure 7(b) were from quasistatic measurements of the differential resistance dV/dI versus I_{dc}, as shown in the inset to Figure 7(b) for a nominally 50-nm diameter contact. The observed peak in dV/dI at $I_{dc} \approx 11\,\text{mA}$ marks the onset of spin-transfer-induced magnetic excitations. Corresponding frequency spectrum measurements showed these dV/dI peaks were actually due to low frequency ($< \approx 2\,\text{GHz}$) noise rather than a coherent high-frequency resonance as in Figure 7(a). This low frequency noise presumably results from switching between multiple metastable magnetic configurations (Pufall *et al*., 2004). Whereas this noise is not due to coherent precession as in Slonczewski (1999), its onset is still due to the spin-transfer torque exceeding a critical value. Therefore, we fit these spin-transfer features using equation (2), but modified for the in-plane magnetic field (Rippard, Pufall and Silva, 2003):

$$I_c = \frac{etM}{\hbar\varepsilon}\left[\frac{23D}{2\hbar\gamma} + 2A\alpha\left(B_{app} + \frac{\mu_0 M}{2}\right)\right] \qquad (3)$$

The fit of equation (3) (dashed line in Figure 7b) gave $\varepsilon \approx 0.14$ and $\alpha \approx 0.08$, in reasonable agreement with the field out-of-plane measurements. Figure 7(b) also shows a fit (solid curve) using the alternate form of equation (3) $I_c \propto (A_{SM} + \Delta A)$, which determined $\delta \approx 70\,\text{nm}$ and $\alpha/\varepsilon \sim 0.15$, or $\alpha \approx 0.02$ assuming $\varepsilon \approx 0.14$. This second form for I_c fits the data in Figure 7(b) much better (reduced $\chi^2 \approx 0.2$ as compared to $\approx$9.5 for equation (3) itself) and gives a more reasonable α. In general, an understanding of the area dependence of spin-transfer resonance is important both for

testing spin-transfer theory and for future applications of spin transfer to magnetic oscillators or nonvolatile memory.

4 PHASE LOCKING BETWEEN SPIN-TRANSFER OSCILLATORS

4.1 Introduction to phase locking

This section reviews data from two independent groups that studied a system of two interacting nanocontact oscillators. The results support a single conclusion: the localized magnetic oscillations of two nanocontact oscillators in submicrometer proximity can phase lock (synchronize) to a single microwave frequency. These investigations, conducted at Freescale Semiconductor (Mancoff, Rizzo, Engel and Tehrani, 2005) and at NIST in Boulder, Colorado (Kaka *et al*., 2005), are motivated by the technological possibilities of increased microwave power output from a large array of phase-locked spin-transfer oscillators. For the present geometry of point contacts to an extended magnetic film, possible coupling mechanisms between contacts include oscillating dipolar magnetic fields, spin-wave radiation, or exchange coupling. A related experiment at NIST demonstrated injection locking of a single spin-transfer oscillator to a microwave current applied from an external source (Rippard *et al*., 2005). In addition, phase locking in arrays of multiple spin-transfer oscillators was recently investigated both by analytical calculations (Slavin and Tiberkevich, 2005) and numerical simulations (Grollier, Cros and Fert, 2005).

Phase locking via mutual interactions occurs in a variety of settings beyond magnetic materials. Examples of solid-state devices include arrays of phase-locked, oscillating Josephson junctions (Wengler, Guan and Track, 1995; Benz and Burroughs, 1991) and Metal-semiconductor transistors (MESFETS) (Popovic, Weikle, Kim and Rutledge, 1991) as well as coupled semiconductor oscillator designs for achieving high-frequency purity (Rohde, Poddar and Bock, 2005). Historically, the first scientific observation of phase locking dates back to 1665 when Christian Huygens noticed synchronized motion of two pendulum clocks caused by mechanical vibrations transmitted through a wall (Bennet, Schatz, Rockwood and Wiesenfeld, 2002). Synchronized behavior also occurs in biological systems, including the light flashing of certain colonies of fireflies in Malaysia (Strogatz, 2003) and the dependence of the periodicity of light emission from individual flies on the received stimulus of neighboring light flashes (Buck and Buck, 1968). Another example is human heart muscle, composed of thousands of pacemaker cells that fire in synchrony to produce a single heartbeat despite slight differences between neighbor cells. However, under certain conditions, synchrony is lost, disrupting the heartbeat and leading to a life threatening medical condition (Strogatz, 2003).

4.2 Measurement of phase locking as a function of contact separation

In this section, we focus on measurements at Freescale on the dependence of phase locking between spin-transfer resonances in two neighboring GMR point contacts as a function of the physical separation between the contacts (Mancoff, Rizzo, Engel and Tehrani, 2005). The two contacts are to the same section of the GMR film and are connected electrically in parallel to each other with a single top electrode (schematic cross section in Figure 8a). The sputter-deposited film consisted of a 5-nm Pd/25-nm Cu base electrode, a 20-nm $Co_{81}Fe_{19}$ fixed magnetic layer, a 6-nm Cu spacer, a 4.5-nm $Ni_{80}Fe_{20}$ free magnetic layer, and a 2-nm Cu/3.5-nm Pd cap. Figure 8(b) shows a cross-section SEM image of the contacts. The center-to-center spacing was 120 nm, and the nominal diameters were 80 nm. As described in the previous section, an actual diameter $d_{SM} \approx 65$ nm was determined

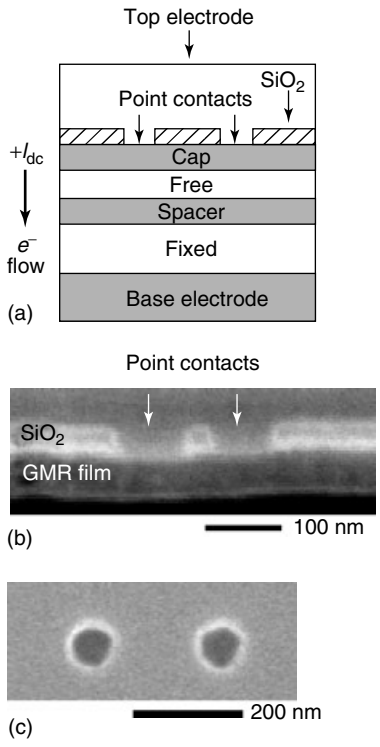

Figure 8. (a) Cross section of two point contacts. (b) Cross-section SEM image of two 80-nm diameter contacts with a 120 nm center-to-center spacing. (c) Plan-view SEM image of two 80-nm contacts with a 240 nm spacing. (Reproduced from Mancoff *et al*., 2005, with permission from Nature Publishing Group. © 2005.)

from a Sharvin–Maxwell calculation. Figure 8(c) is a plan-view SEM image of a similar sample with 240 nm spacing.

For high-frequency measurements on double point contacts in this section, a total dc current I_{dc} was applied to the contact pair. Figure 9 shows the measured frequency spectrum voltage amplitude versus I_{dc} for three devices with center-to-center spacings of 800 nm (Figure 9a), 150 nm (Figure 9b), and 120 nm (Figure 9c). All the data in this section was taken in a magnetic field of between 0.8 and 1.2 T applied perpendicular to the plane of the film. The spin-transfer precession, or resonance, appeared as a frequency spectrum peak at a given I_{dc}. The peak frequencies for all spacings increased approximately linearly with increased I_{dc}, over a frequency range of <10 to >24 GHz, in agreement with similar measurements on single GMR point contacts (Rippard *et al*., 2004a; Mancoff, Rizzo, Engel and Tehrani, 2006). The number and behavior of the observed spin-transfer peaks depended on the two contacts' relative spacing. For the widely spaced device (Figure 9a) with 800 nm spacing, we observed two separate peaks for nearly all I_{dc}. The two peaks had comparable resonance frequencies that increased at similar average rates versus I_{dc}. Each peak displayed frequency jumps at multiple I_{dc} values, similar to discontinuities observed for single point contacts (Rippard *et al*., 2004a; Mancoff, Rizzo, Engel and Tehrani, 2006). The two sets of jumps were uncorrelated, so the pair of contacts at 800 nm spacing was undergoing independent, uncoupled spin-transfer oscillations.

In contrast, the closely spaced contact pair (Figure 9c) at 120 nm spacing displayed only a single peak in frequency for all I_{dc}. The change from two independent peaks at 800 nm spacing to a single peak at 120 nm spacing indicates interactions between the point contacts at closer spacing coupled the spin-transfer oscillations. The coupling strength is sufficient to bring together in frequency the resonances from the two different contacts that would otherwise be separated by several hundred megahertz for uncoupled devices, as in Figure 9(a). For the device with a somewhat greater spacing of 150 nm (Figure 9b), we detected two separate peaks for most I_{dc}. However, here the two peaks progressed nearly parallel in frequency versus I_{dc}, compared to the two independent sets of frequency jumps for the 800 nm

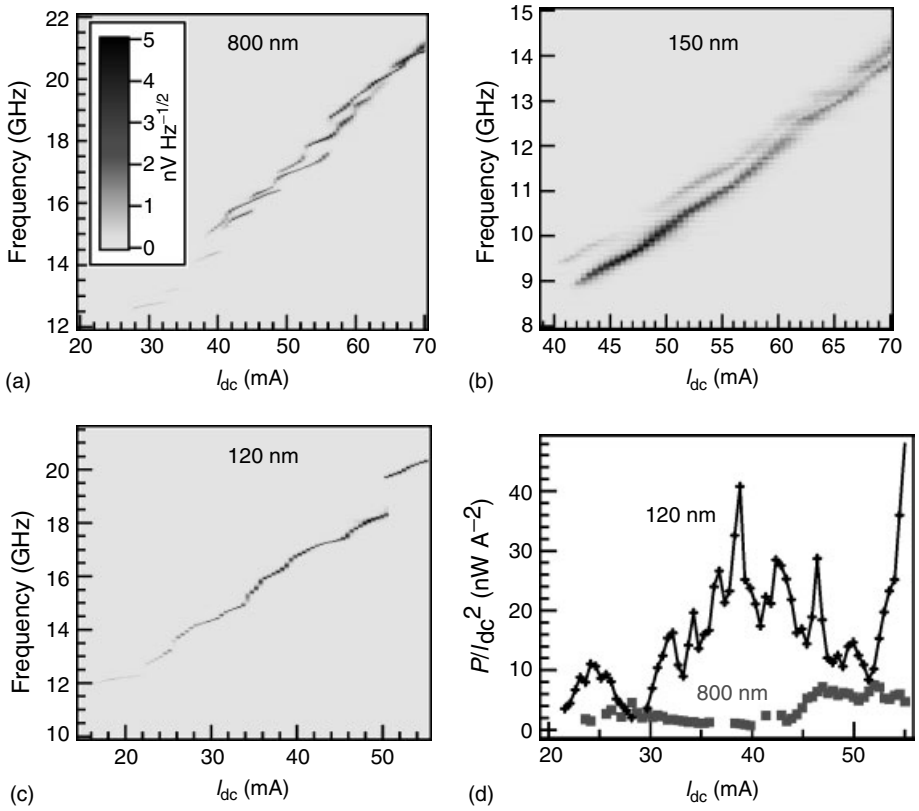

Figure 9. Maps of spectrum amplitude versus frequency and applied current bias I_{dc} for devices with varied center-to-center intercontact spacing of (a) 800 nm, (b) 150 nm, and (c) 120 nm. (d) Integrated power P normalized by I_{dc}^2 versus I_{dc} for double point contact devices with 120 nm (crosses) and 800 nm (squares) spacings. Corresponding frequency spectra show either one or two spin-transfer peaks, respectively. The curve for the 800-nm spaced sample includes the sum of the power in its two peaks. (Reproduced from Mancoff *et al*., 2005, with permission from Nature Publishing Group. © 2005.)

spacing device (Figure 9a). Thus, the 150 nm spacing data in Figure 9(b) behaved with a coupling strength intermediate between the two independent peaks at 800 nm spacing and the single peak at 120 nm spacing.

We observed a significant difference in power output between devices with a relatively close spacing and a single resonance peak compared to devices with larger spacing and two independent peaks. Figure 9(d) shows that the typical integrated power normalized by $I_{dc}{}^2$ for the single peak in a device with 120 nm spacing (crosses) was clearly greater than the combined power for the two peaks in a device with 800 nm spacing (squares). Among seven devices (with spacings of 120–200 nm) showing a single peak similar to Figure 9(c), the average output power was $11 \pm 2\,\mathrm{nW\,A^{-2}}$ (where specified uncertainty is the standard error) in 1 T applied magnetic field. In contrast, for all seven devices (with spacings of 400 and 800 nm) showing two independent peaks similar to Figure 9(a) the average output power was $5 \pm 0.5\,\mathrm{nW\,A^{-2}}$ for the two peaks combined in a 1 T field. A similar factor of ≈2 difference in power was also observed in 1.2 T, with $8 \pm 1\,\mathrm{nW\,A^{-2}}$ for devices with small spacing and one peak and $4 \pm 0.5\,\mathrm{nW\,A^{-2}}$ for devices with large spacing and two peaks.

The factor of ≈2 difference in output power indicates the closely spaced double point contacts were phase locked. We modeled the two contacts as resistors R_1 and R_2 in parallel with each other and in series with a single current source I_{dc}. The two resistances oscillate in time with a phase difference ϕ and equal amplitude ΔR and frequency ω about an average value R_0: $R_1(t) = R_0 + (\Delta R/2)\cos\omega t$ and $R_2(t) = R_0 + (\Delta R/2)\cos(\omega t + \phi)$. The ac voltage V_{ac} generated by the device is then $V_{ac}(\phi) = I_{dc}\,((R_1R_2/(R_1 + R_2)) - (R_0/2))$, and the power measured across the 50 Ω load of the spectrum analyzer is $P(\phi) = \frac{1}{2} \cdot (V_{ac}^2(\phi)/50\,\Omega)$. For simplicity, we assumed the 50 Ω load impedance is much greater than the contact resistances, as is in the experiment. The power for two in-phase oscillators is found by evaluating $P(\phi = 0)$. The power for two uncoupled contacts oscillating independently with random ϕ, as expected in Figure 9(a), is given by averaging over ϕ from 0 to 2π: $P_{\mathrm{random}\,\phi} = \int_0^{2\pi} \frac{P(\phi)\mathrm{d}\phi}{2\pi}$. Evaluating these expressions, we find: $P(\phi = 0) = 2P_{\mathrm{random}\,\phi}$, so that the modeled total power for two uncoupled contacts is half the power for two in-phase oscillators. Thus, we conclude that the two point contact oscillators with close intercontact spacing (Figure 9c) are phase locked with $\phi = 0$, whereas those with wide spacing (Figure 9a) are uncoupled.

We measured spin transfer in over 30 devices with various spacings and repeatedly observed the trend in Figure 9(a–c). The statistical distributions for these measurements are shown in Figure 10 where we plot histograms for the three types of spin-transfer frequency-domain behavior (two peaks, intermediate, and one peak) versus intercontact spacing. The solid lines are guides to the eye. The 'two peaks' histogram (solid diamonds) is maximum for the largest spacings of 400 nm and greater and drops to 0 at small spacings. These data correspond to devices with two spin-transfer peaks observed at each I_{dc} and with each peak showing its own independent frequency jumps, indicating that the point contact pair was uncoupled. The 'one peak' histogram (open squares) is maximum at the smallest spacings of 120–150 nm and decreases to 0 above 200 nm. These data correspond to devices with a single resonance peak observed at each I_{dc}, indicating strong coupling and associated phase locking between the oscillators. Finally, the 'intermediate' histogram (solid triangles) shows a third category of spin-transfer data with a maximum around 200 nm spacing. These data correspond to devices which showed a transition from one peak to two within an I_{dc} sweep, or a single peak over most I_{dc} values with an occasional weaker second peak, or two peaks moving nearly parallel in frequency with I_{dc} as in Figure 9(b). This intermediate category represents devices in a transition range between those with strong coupling with phase locking and those with very weak or no coupling between the two independent oscillators.

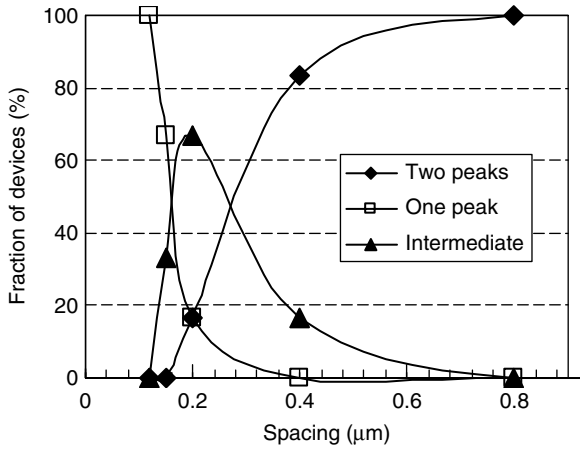

Figure 10. Histogram of spin-transfer behavior for devices with two contacts and varied center-to-center spacing. Squares show the devices for which a single spin-transfer peak was observed, as in Figure 9(c). Diamonds show the devices for which two peaks were observed, as in Figure 9(a). Triangles show the devices with intermediate spin-transfer characteristics. Solid lines are guides to the eye. (Reproduced from Mancoff *et al.*, 2005, with permission from Nature Publishing Group. © 2005.)

Figure 10 indicates consistent likelihood of phase locking in the Freescale double point contact devices at center-to-center spacings <200 nm. As described in the previous section, the region of large-angle precession for each point contact exceeds the physical contact area in the extended $Ni_{80}Fe_{20}$ free layer magnetic film. For a single contact

of nominally 80 nm diameter (with a Sharvin–Maxwell diameter $d_{SM} \approx 65$ nm, as described in the previous section), we estimated an effective magnetic excitation diameter of approximately 170 nm (Mancoff, Rizzo, Engel and Tehrani, 2006). This value suggests the possibility that an overlap in the regions of strong dynamic excitation existing for center-to-center spacings of 200 nm (Figure 10) leads to a spontaneously phase-locked state above the critical current of the oscillators. We see in the next section that phase locking can occur for a larger contact separation (500 nm) with the requirement that each oscillator's resonance frequency be independently tuned to closely coincide.

Figure 11 gives another example of spin-transfer oscillations in a double point contact device with 150 nm intercontact spacing and an intermediate coupling strength. For the frequency spectra map versus I_{dc} in Figure 11(a), we observed the onset of one spin-transfer peak for $I_{dc} > \approx 28$ mA followed by a second peak of comparable amplitude for $I_{dc} > \approx 35$ mA. The two separate peaks then coexisted for I_{dc} up to $\approx$47 mA followed by a transition to a single peak above this current, likely indicating that the contacts have phase locked. Figure 11(b) shows the corresponding integrated output power normalized by ${I_{dc}}^2$. The closed triangles are for the single peak at high I_{dc}, whereas the open squares and closed diamonds are the individual powers in the two peaks at lower I_{dc}, with the open squares (closed diamonds) showing the data for the lower (higher) frequency peak of these two. We observed an average power $\approx 5\,\mathrm{nW\,A^{-2}}$ in each of the two peaks with a total $\approx 10\,\mathrm{nW\,A^{-2}}$ just below the transition at $I_{dc} \approx 47$ mA, as compared to $\approx 20\,\mathrm{nW\,A^{-2}}$ in the single peak at higher current. This factor of 2 power increase is consistent with phase locking with $\phi = 0$, as discussed in the preceding text. Thus, Figure 11 illustrates an electrically tunable transition of the double point contact device into phase locking. For this device, the linewidth *FWHM* decreases across the transition, from $\approx$200 MHz for each of the two peaks at low I_{dc} narrowing to $\approx$80 MHz for the single peak at high I_{dc}.

A decreased linewidth upon phase locking is expected if thermal fluctuations contribute significantly. Then for the phase-locked pair, thermal energy fluctuations act on a device with greater coherent magnetic volume, so the effective fluctuation field and *FWHM* will decrease, as in Figure 11 (Russek *et al.*, 2005). On average, we observed a slight ($\approx$10–30%) decrease in the *FWHM* for the closely spaced devices with one peak compared to $\approx$200 MHz *FWHM* for widely spaced devices with two peaks.

In this section, the Freescale devices with two nanosized spin-transfer oscillators in parallel phase locked when the intercontact spacing was <200 nm. We observed only one resonance for closely spaced contacts and found the average power was approximately twice the total for two separate resonances at large spacings, indicating phase locking for the closely spaced contacts.

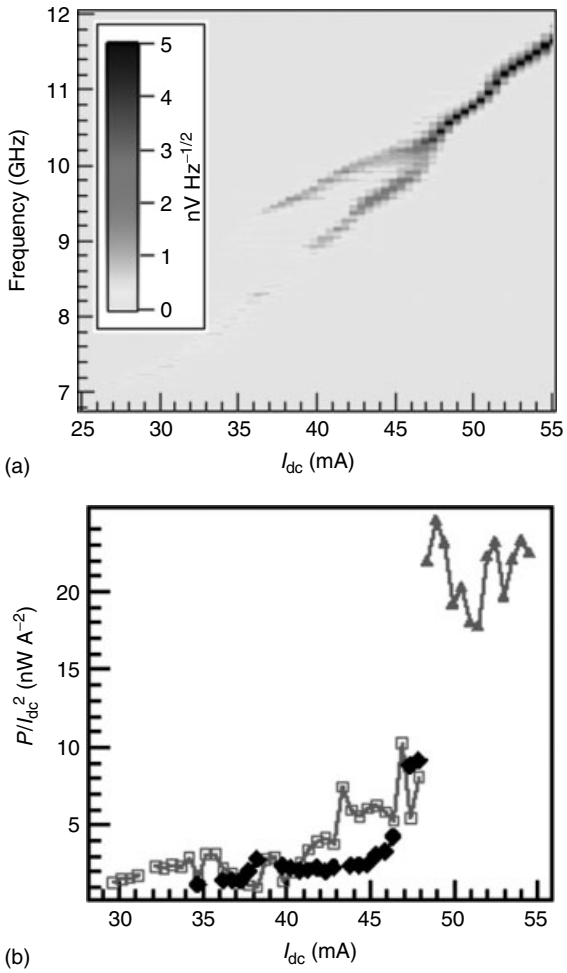

Figure 11. (a) Map of spectrum amplitude versus frequency and applied current bias I_{dc} for two contacts with 150 nm intercontact spacing. (b) Integrated power P normalized by I_{dc}^2 versus I_{dc} for the frequency spectra in (a). The data for I_{dc} below the transition at $\sim$47 mA is given by the open squares and closed diamonds for the lower and higher frequency peaks respectively. Closed triangles show the data for the single peak observed at larger I_{dc}. (Reproduced from Mancoff *et al.*, 2005, with permission from Nature Publishing Group. © 2005.)

4.3 Measurement of phase locking with independent frequency control of each oscillator

In this section, we discuss measurements at NIST on the two-nanocontact system utilizing a slightly different device structure and measurement method (Kaka *et al.*, 2005). Sputter-deposited spin valve films were patterned into 10 μm × 20 μm rectangular mesas with the following

layer structure: 5-nm Ta/50-nm Cu/20-nm $Co_{90}Fe_{10}$/5-nm Cu/5-nm $Ni_{80}Fe_{20}$/1.5-nm Cu/2.5-nm Au. The $Co_{90}Fe_{10}$ layer is the fixed layer of the spin valve because its moment and thickness are larger than the $Ni_{80}Fe_{20}$ layer. E-beam lithography was used to pattern two 40-nm diameter metallic contacts (nanocontacts) to the top of the mesa through a PMMA insulator. The contacts were separated by 500 nm and wires were fabricated connecting each nanocontact to a separate set of probe pads. Ground contacts are made to the sides of the mesa. This device structure (Figure 12a) allows independent current control of each contact. Each nanocontact is connected to its own current source through the inductive port of a bias tee (Figure 12b). The capacitive port of each bias tee transmits the high-frequency output of each device, when active. Both of these high-frequency channels are input to the isolated ports of a microwave power combiner that has a bandwidth of 2–18 GHz. The output of the power combiner is amplified and then measured by a spectrum analyzer. When both nanocontacts are active, and their respective frequencies are within the bandwidth of the power combiner, then the high-frequency signals from both contacts can be displayed simultaneously. All the data in this section were taken with an external magnetic field of 0.74 T oriented at 75° from the film plane. This particular applied magnetic field vector is known to produce relatively high output power from a nanocontact oscillator (Rippard *et al*., 2004b).

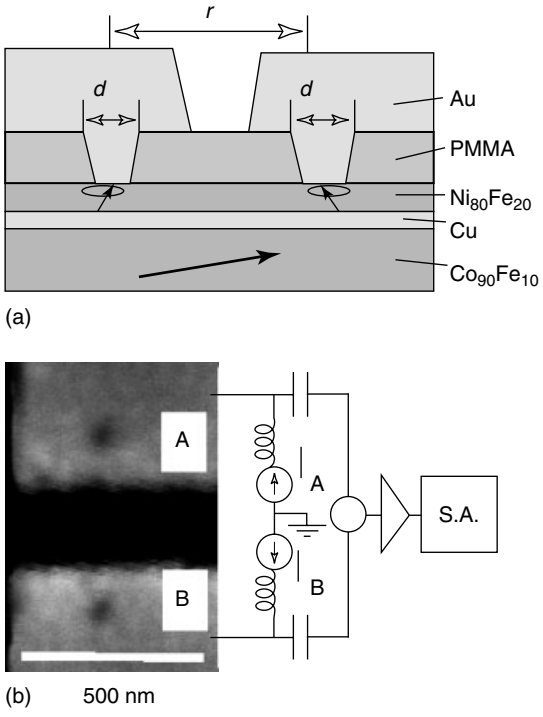

Figure 12. (a) Cross section of two nanocontacts (with diameter $d = 40$ nm) made to a spin valve stack. The contacts were separated by $r = 500$ nm. Arrows show assumed magnetization directions and motion. (b) Micrograph of a two-nanocontact device. At right is a measurement schematic including a bias tee connected to each contact, a microwave power combiner (circle), an amplifier, and the spectrum analyzer (designated by S.A.). (Reproduced from Kaka *et al*., 2005, with permission from Nature Publishing Group. © 2005.)

When only one oscillator was active (no current through the other contact), we detected the noninteracting (free-running) behavior of that particular oscillator. Figure 13(a) shows the free-running peak frequencies for each oscillator as a function of applied current. The two oscillators are designated as A and B. Figure 13(b) shows the output power (area under the spectral peak) in the free-running state for A and B. The frequencies exhibited by both oscillators were close to previous measurements in nanocontact oscillators at this particular field and angle (Rippard *et al*., 2004b). However, small differences existed in the frequency and power output of each oscillator. This difference, possibly due to slight variations in the geometry of the fabricated contacts, enabled unique identification of each oscillator.

When currents were applied to both contacts making both oscillators simultaneously active, interactions between the oscillators altered their frequencies from their free-running values. First, there was a static oersted magnetic field generated by the current through the neighboring contact. An estimate of the in-plane field at a neighboring contact can be given by the simple formula of field from an infinite current: $B = \mu_0 I (2\pi r)^{-1}$. For a 12 mA current and a 500 nm separation, the estimated field is only 4.8 mT, whereas the in-plane component of the applied field in our measurement was 191.5 mT. The result of this additional small oersted field was an approximately linear shift in the oscillator frequency as a function of current through the *other* contact as seen in Figure 14. This effect persisted for negative current through

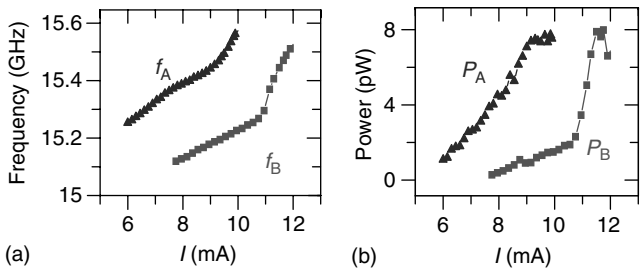

Figure 13. Free-running oscillator behavior. (a) Frequency of oscillator A alone versus current through A (triangles). Frequency of oscillator B alone versus current through B (squares). Figure 14. Effect of oersted field from neighboring contact on oscillator frequency. Frequency of oscillator B versus current through contact A.

the other contact (the other oscillator is inactive), and the slope of the frequency shift with current changed sign if the sign of the applied field was switched.

Second, and more remarkably, a mutual nonlinear interaction between the two oscillators led to phase coherence of both oscillators at a single frequency over a range in applied current. This behavior was experimentally examined through the following protocol: current through A (I_A) was fixed at 8 mA, current through B (I_B) was ramped, and at each point during the ramp, the spectrum of the combined signals from A and B was detected. Figure 15(a) shows the evolution of the spectrum as I_B is ramped for a particular device. Color on the contour plot represents spectral intensity. Initially, only the signal from A was present. As I_B was ramped, a signal from B emerged above its critical current, and the frequency increased with the same slope as its free-running case. In addition, the frequency of A decreased slightly because of the ampere field from current through B. Figure 15(b) shows the spectrum consisting of both peaks at $I_B = 8.65$ mA. Near $I_B = 9.2$ mA, both oscillators suddenly united to produce a single frequency. This locked state remained until about $I_B = 11$ mA. Above 11 mA, the system unlocked, and two separate signals reemerged. The spectrum of the locked state in Figure 15(c) ($I_B = 9.5$ mA) was a peak that was both narrower and much stronger than either peak in Figure 15(b).

The high-frequency signal from each individual oscillator as it evolved through locking was accessed by disconnecting the other oscillator's high-frequency channel from the power combiner. The results are shown in Figure 16. Both oscillators emitted at the same frequencies for $I_B > 9.2$ mA, albeit with very different power output. Figure 16(b) shows that power from A was roughly constant at 4.2 pW (the

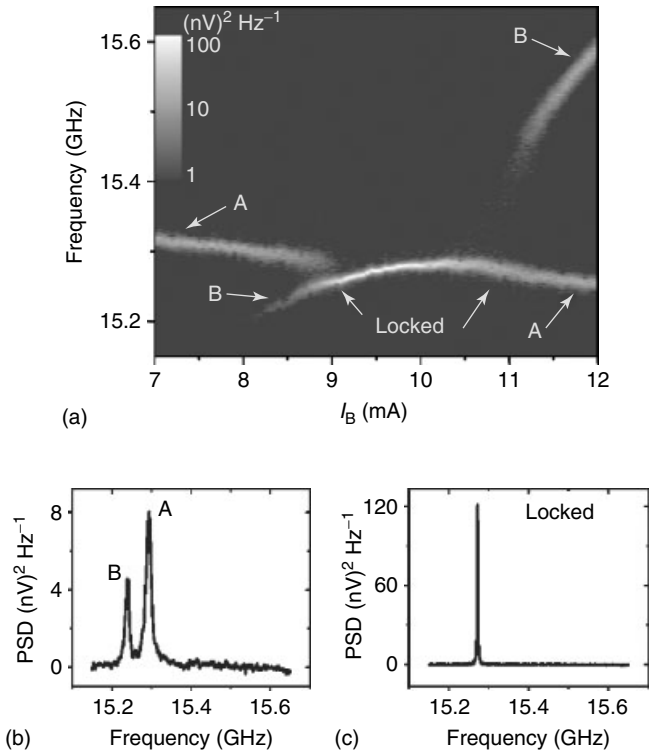

Figure 15. (a) Contour plot showing the evolution of spectra from both oscillators as current through A was fixed at 8 mA and current through B was ramped from 7 to 12 mA. Spectral intensity is on a logarithmic scale. Locking occurred in the region where only one frequency was present. (b) Spectrum taken before locking occurred showing peaks for A and B. Current through B is 8.65 mA. (c) Spectrum of locked state. Only one peak was visible. Current through B was 9.5 mA. (Reproduced from Kaka *et al*., 2005, with permission from Nature Publishing Group. © 2005.)

free-running power at $I_A = 8$ mA) until B activated. Interaction with B caused the power from A to vary, and during locking, power from A increased. As seen in Figure 16(d), the power from oscillator B increased with current much like in its free-running condition. The spectral linewidths, measured as the *FWHM* of the signal peaks, abruptly decreased during locking. This is shown in Figure 17 for both oscillators. During locking, the linewidth was about 2 MHz. In comparison, the free-running oscillator linewidths were greater than 4 MHz. Apparently the feedback mechanism that sustained a phase-locked state also ensured greater frequency stability of the oscillators.

The phase coherence of the two oscillators during locking was demonstrated by including a phase shifting coaxial element in the high-frequency channel of A leading to the power combiner. I_A was again fixed at 8 mA, and I_B was fixed at 9.55 mA to lock both oscillators. The phase shifter was fully adjusted producing about a 300° change in phase length between the two high-frequency channels.

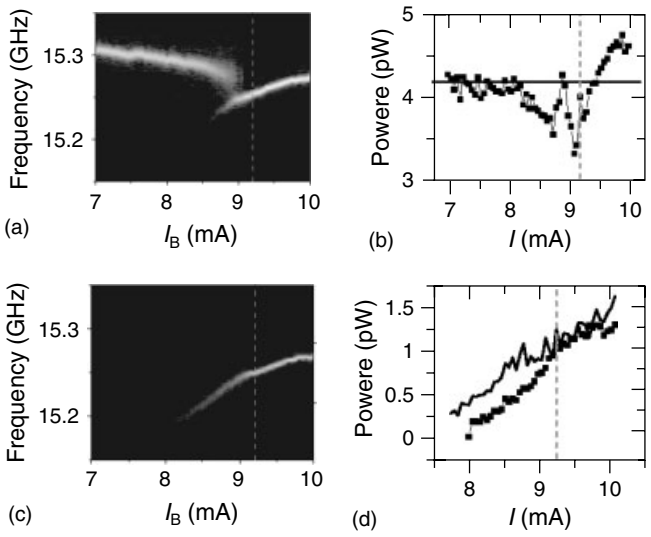

Figure 16. Behavior of individual oscillators. Start of the locking range indicated by vertical dashed line in each panel. (a) Evolution of spectra from A only as current was ramped through B. A was still fixed with current of 8 mA. (b) The power from A only (squares) varied as A interacted with B. The free-running power from A when current through A was 8 mA (line) is also shown. (c) Evolution of spectra from B only as current was ramped through B. (d) Power from B only (squares) increased with current. The free-running power from B versus current through B (line) is also shown. (Reproduced from Kaka *et al*., 2005, with permission from Nature Publishing Group. © 2005.)

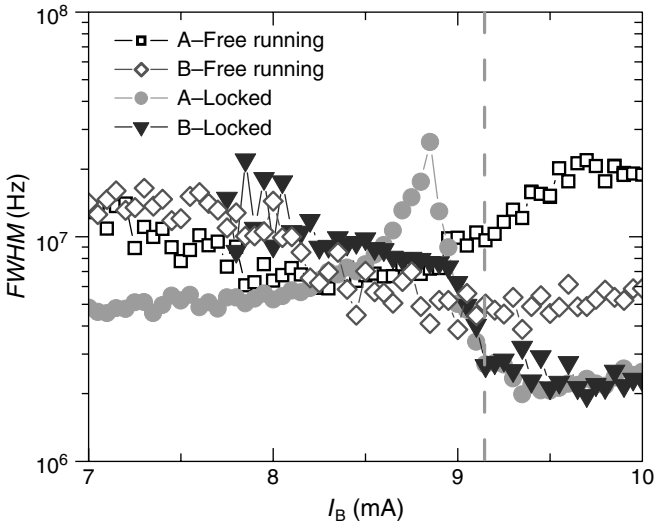

Figure 17. Free-running linewidths with current for A (open squares) and B (open diamonds) are shown. Linewidths for the interacting oscillators A (solid circles) and B (solid triangles) showed an abrupt drop at locking. Onset of locking is designated by the vertical dashed line. (Reproduced from Kaka *et al*., 2005, with permission from Nature Publishing Group. © 2005.)

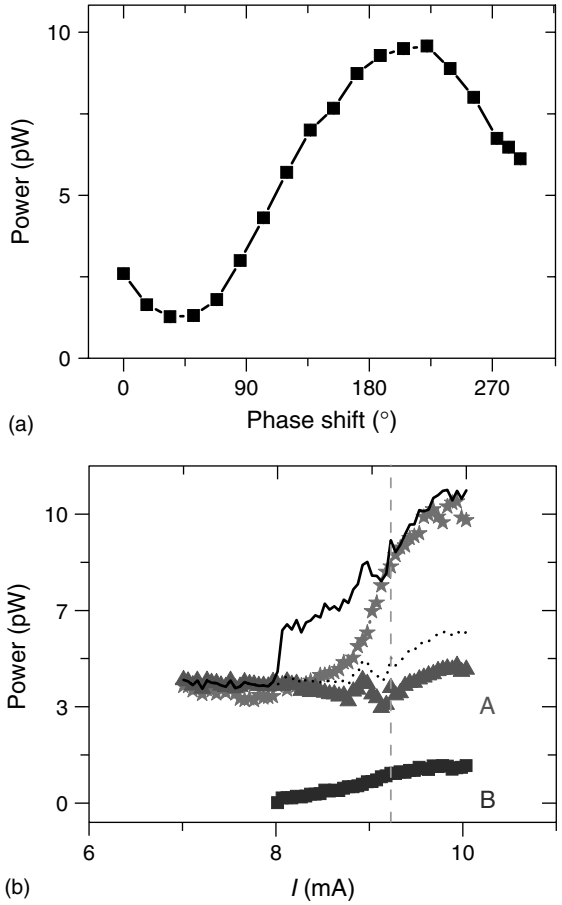

Figure 18. (a) Combined power output versus phase shift where the current through A was 8 mA and the current through B was 9.55 mA. An interference pattern between signals from A and B resulted. (b) Power outputs versus current through B. Power from A only (triangles), power from B only (squares), and combined power (stars). Sum of power from A and B (dotted line) and coherent sum of power from A and B (solid line) are also shown. The vertical dashed line indicates the start of the locking range. (Reproduced from Kaka *et al*., 2005, with permission from Nature Publishing Group. © 2005.)

The resulting combined power as the phase was shifted is shown in Figure 18(a). The sinusoidal variation in time-averaged power as the phase was shifted is an interference pattern that can only occur because of a time-independent phase relationship between the signals from A and B. Although the data shows that A and B were phase coherent during locking, we have not determined the absolute phase difference (if any) between the oscillations of A and B. However, this phase difference could be determined using this measurement method if the phase length of each high-frequency channel is known.

With the phase shifter set to maximize the combined output with $I_A = 8\,\text{mA}$ and $I_B = 9.55\,\text{mA}$, the power measured was $P_{MAX} = 9.90\,\text{pW}$. Here, the phase shifter adjusted the

phase length such that the signals from A and B were in phase at the power combiner. At those same currents, the individual oscillator powers were 4.37 and 1.19 pW from A and B respectively. A and B were phase coherent ac voltage sources, thus the combined output power was the coherent sum given by $P_c = (V_A + V_B)^2(50\,\Omega)^{-1} = P_A + P_B + 2(P_A P_B)^{1/2}$ where V_i and P_i are the individual oscillator voltage and power output respectively. The coherent sum should be 10.15 pW, which is close to P_{MAX}. Conversely, if A and B were coincidentally at the same frequency but not phase coherent, the time-averaged combined power would be given by $P = ({V_A}^2 + {V_B}^2)(50\,\Omega)^{-1} = P_A + P_B = 5.56$ pW. Figure 18(b) shows the measured combined power as well as the individual output powers. A dotted line is added to represent $P_A + P_B$, which is substantially less than the combined power during locking. Outside the locking range, the measured combined power (power from both peaks) was less than the calculated coherent sum of power, yet during locking the calculated coherent sum and the actual measured combined power matched well. Maximized power output by coherent addition is an important and perhaps useful property of phase-locked nano-oscillators that can lead to significantly increased output levels for applications.

5 DEVICE APPLICATIONS OF SPIN-TRANSFER OSCILLATORS

Synchronized nanocontact oscillators can potentially both compete with existing microwave oscillators and drive new applications. A single oscillator produces a wide range of microwave frequencies depending on current and applied field. The high-frequency output typically has narrow linewidth, that is, a high-frequency stability, as characterized by a quality factor *f/FWHM*, where f is the oscillator frequency and *FWHM* is the full-width at half-maximum of the spectral peak. Quality factors from 10^2 to 10^4 have been demonstrated (Rippard *et al*., 2004b). Furthermore, the oscillations are generated from a small footprint device. As mentioned previously, the region of large-angle magnetic precession is of the same order as the contact area (diameter ≈100 nm). The full device dimensions are determined by the magnetic mesa size, which is several micrometers on a side. In contrast, commercially available tunable oscillators depend on resonators, such as quartz crystals, yttrium-iron-garnet (YIG) spheres, and LC networks, which have footprints ≈1 mm on a side (Burns, 2003; Rohde, Poddar and Bock, 2005). Finally, the nanocontact oscillator is fabricated using standard sputtered magnetic thin films. This technology is compatible with both MRAM (Åkerman *et al*., 2004) and mainstream complementary metal oxide semiconductor (CMOS) fabrication, permitting cost effective manufacturing.

Synchronized nanocontact oscillators allow for increased high-frequency power output. At present, the output from a single nanocontact oscillator has been measured as high as few nanowatts. By coherently combining the power from N phase-locked oscillators electrically connected in a series array, for example, the output power to a load should increase as N^2 in the case where the load resistance is much greater than the array resistance. In addition to the increased power, phase-locked spin-transfer oscillators also appear to provide enhanced frequency stability.

Certain challenges exist to take advantage of spin-transfer nanocontact oscillators in applications. Nanocontact oscillators require a large magnetic field directed out of plane to produce the highest output powers (Rippard *et al*., 2004b). This field could be introduced by compact permanent magnets by an appropriate exchange bias. Another concern is the efficiency of converting the dc input power to high-frequency output power. For example, 10 mA is typically sufficient to produce oscillations in a 20 Ω GMR device leading to an input power P_{dc} of 2 mW. The output power P_{ac} is in the picowatt to the nanowatt range, yielding efficiencies P_{ac}/P_{dc} from 10^{-8} to 10^{-6}. Replacing the GMR signal ≈1% with a tunneling magnetoresistance (TMR) signal of 100–200% for MgO-based tunnel junctions could dramatically increase the efficiency. For either GMR or TMR devices, the substantial dc current to excite spin-transfer oscillations can create difficulties from electromigration, heating, or tunnel barrier breakdown. Materials engineering, which has been successful for developing disk drive read heads and MRAM bits, may lead to an optimized device structure containing a proper internal magnetic field bias and requiring less current. Finally, a microwave design needs to be developed that allows for dc current biasing and high-frequency power combining of an array of phase-locked nanocontact oscillators.

Spin-transfer oscillator properties allow for exciting application possibilities. Compared to typical voltage controlled oscillators, spin-transfer oscillators can offer wide frequency tunability, small device size, and fast modulation capability (Pufall *et al*., 2005). One application is as reference oscillators for portable electronics and communications. The footprint of a nanocontact oscillator array is 10 μm on a side. The conventional timing reference in cellular phones, for example, is a crystal oscillator with a footprint of a few millimeters. The much smaller magnetic oscillator array would allow the direct integration of the timing source within a single transceiver communications chip. The small footprint, high frequency, and frequency agility of the nanocontact oscillators may lead to application as a local oscillator within a heterodyne detector. This could provide RF spectrum analysis within a single chip. Finally, magnetic nanocontact oscillators may find application within a wireless communication

system that operates between the separate components within a computer, enabling the fast electronic data transfer that is increasingly important as computer systems move toward multiprocessor parallel computing schemes.

6 SUMMARY

When biased with a dc current, lithographic point contacts to GMR films can produce a microwave signal due to spin-transfer resonance. The frequency is tunable from at least 5–40 GHz as a function of current and magnetic field, and the linewidths can be as narrow as <5 MHz with resonance quality factors exceeding 10 000. We examined the area dependence of spin-transfer precession and also observed phase locking between neighboring excitations. First, as a function of nominal contact diameter from 50 to 300 nm, devices at Freescale showed a decreasing slope of precession frequency versus current and an increasing critical current. This data was fit using a model in which the magnetically precessing region extends beyond the contact edge by a ring of width ≈50 nm. Other effects, such as the oersted field, the spin-wave radiation pattern, and other magnetic nonuniformities with a more detailed spatial dependence than can be accounted for with this model, may also affect the size dependence.

With regard to phase locking, experiments at Freescale detected phase locking between two nominally 80-nm diameter spin-transfer oscillators, electrically connected in parallel to a single top electrode, when the intercontact spacing was $< \approx$200 nm. On average, the total power in the single resonance peak for these closely spaced devices was approximately twice the combined power in the two separate peaks observed for devices with two widely spaced contacts. The experiments at NIST examined devices with independent electrical control of two nanocontact oscillators spaced by 500 nm and found that the two resonances phase locked when the current bias through one contact was varied so as to shift its frequency close to that of the second contact. The difference in the spacing length scale for phase locking is not fully understood and may be due to the different bias geometries, for which the independent electrical biasing in the NIST experiment may permit more precise frequency matching and longer-range phase locking. Further experiments may also identify the coupling mechanism that causes phase locking, such as spin-wave radiation or oscillating magnetic fields emitted by each contact. The increased output power and decreased resonance linewidth for phase-locked contacts promise to enable control of even larger arrays of spin-transfer oscillators and make possible new applications for these devices in microwave electronics.

Theory of Spin-polarized Current and Spin-transfer Torque in Magnetic Multilayers

John Slonczewski[1]

IBM Research Division, Yorktown Heights, NY, USA

[1] *IBM RSM Emeritus*

1 INTRODUCTION

In 1996, Luc Berger predicted that electric current flowing across a normal metal spacer between two magnets could excite forward-propagating spin waves (Berger, 1996). In the same year, a ballistic model predicted that a steady current may create a spin-transfer torque that would excite magnetic precession in one of two so separated single-domain magnets having lithographed dimensions of order 100 nm (Slonczewski, 1996). If the sign of uniaxial anisotropy is negative, this precession may remain steady, making conceivable a radio frequency oscillator. If the anisotropy is positive, a spiral precession followed by magnetic reversal may occur, in which case writing for magnetic memory is conceivable. Subsequent experiments supported these predictions and led to the vast array of new spin-transfer phenomena under investigation today (Stiles and Miltat, 2005).

However, the first copious experimental evidence for any current-driven magnetic excitation was that of Tsoi *et al*. (1998), who passed currents through mechanical point contacts into unpatterned (not single-domain) multilayers. In the absence of lithography, spin waves radiate energy transversally away from the contact region, greatly increasing the current required for excitation (Slonczewski, 1999). The year 1999 saw the beginning of monodomain excitation in magnets having lithographic dimensions $\leq$150 nm. In one case a magnetic oxide particle was excited, (Sun, 1999) and in another, one layer of a lithographed all-metallic multilayer (Myers *et al*., 1999).

Equivalent circuits of spin-polarized current play a large role in the theory of giant magnetoresistance and spin-transfer torque (Brataas, Nazarov and Bauer, 2000; Brataas, Bauer and Kelly, 2006). Sections 2–4 present a *majority-spin transparency* model for diffusive noncollinear magnetoresistance and current-driven torque (Slonczewski, 2002). It takes explicit account of the band structures of the elements Co, Ni, and Cu used in many experiments. The question of torque is reduced to that of solving an effective circuit whose branches consist of the four spin-channel currents flowing through the two ferromagnets in a device pillar. The key formulas for cross-spacer connection of spin-channel voltages and currents enable algebraic solution of effective circuit equations.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

Their application predicts the currents and torques, requiring only prior analytic solution of the linear coupled diffusion equations (Valet and Fert, 1993) governing the current-voltage relations of the separate halves of the device pillar (see also **Theory of Spin-transfer Torque, Volume 2**).

Section 5 illustrates theoretical results for currents and torques for the simple case of a symmetric pillar with purely resistive spin channels lacking spin relaxation. Section 6 presents the barest essentials of the magnetic dynamics resulting from spin-transfer torque. It assumes uniaxial anisotropy and illustrates both the switching and steady precession of a monodomain produced by a steady electric current.

More recently, spin-transfer switching was also observed in magnetic tunnel junctions (MTJs). Two laboratories, at Grandis, Inc. (Huai *et al*., 2003) and Cornell U., (Fuchs *et al*., 2004) reported it independently, thus making possible higher signal voltages in spin-transfer memory elements. Sections 8 and 9 treat noncollinear magnetoresistance and spin-transfer torque for the case of MTJs, employing Bardeen tunneling theory, introduced in Section 7.

For a given voltage V, one has the two-parameter formula $J = VG_0(1 + g\cos\theta)$ for the electric current density versus the angle θ between the moments. Section 8 presents the theory for left and right-torque densities $(\hbar/2e)VG_0\tau_{L,R}\sin\theta$ with respective dimensionless coefficients $\tau_L$and τ_R. Assuming elasticity of the tunneling and validity of the polarization factors P_L, P_R for the two electrode-and-barrier compositional combinations, one predicts the mutual relation $g = \tau_L\tau_R$, with $\tau_L = P_R$ and $\tau_R = P_L$.

The concept of polarization factor is less convenient at the high voltages and small barrier thicknesses needed in devices, for then inelastic tunneling becomes more important. Responding to the recent advent of very highly magnetoresistive MTJs with MgO barriers, Section 9 describes an appropriate phenomenological model which concludes with predicted observational signatures of conductance and torque caused by special conditions at the ferromagnet-insulator interfaces.

2 TWO-CHANNEL SPIN-POLARIZED TRANSPORT

2.1 Suppression of transverse polarization

The internal exchange field giving rise to the spontaneous magnetization of a ferromagnet such as Fe, Co, or Ni is so strong that, in equilibrium, it creates a relative shift eV_{ex} between spin-up and spin-down energy bands amounting to about 2 eV for Fe and Co, and 1 eV for Ni. Suppose that an additional out-of-equilibrium electron should initially occupy a state in which the spin lies orthogonal to the spontaneous magnetization. It then precesses at this terrific frequency $eV_{ex}/\hbar$ which is orders of magnitude greater than the frequencies (in gigahertz) encountered in the magnetic dynamics of nanoscale device elements described by classical Landau–Lifshitz equations. Consequently, the transverse polarization and its current are very strongly suppressed within the thickness ($\geq$3 atomic layers) and time scales (>100 ps) of usual interest in magnetic memory.

More precisely, it is not exchange alone, but a *combination of three effects* which creates such a strong exchange splitting of those band regions near the Fermi surface which are important in electron transport. To begin, a free atom of Fe, Co, or Ni has the electron configuration $3d^n4s^2$ outside of the argon core. The values of n are 6 for Fe, 7 for Co, and 8 for Ni. When the atoms bond to form a pure metal, the strong spin-diagonal (nonexchange) crystalline electric field causes two effects. The first effect is that the electrostatic field of neighboring point-charge nuclei disrupts the atomic orbitals and 'quenches' the atomic-orbital angular momentum, thus suppressing to a degree spin relaxation via spin-orbit coupling. Secondly, it permits electron waves at the Fermi level to propagate with relative freedom through the lattice. Quantum-mechanically, both of these effects cause the atomic s ($l = 0$) wave functions to mix strongly with p ($l = 1$) and d ($l = 2$) wave functions. Indeed, the sheer number of p (3) and d (5) states is so great compared to the one s state per atom, that none of the band states at the Fermi surface have predominantly s character. (The one-electron V_{sd} matrix element in first-principle band structure computations is of order 1–2 eV.) Thirdly, it follows that this mixing generally subjects the Fermi-energy electrons to the mean-field atomically *internal* d–d exchange interaction. This exchange is extremely large, amounting to a level splitting of order $J_{dd} \approx$ 1–2 eV. Generally, very few of the wave functions approach the character of 4s or free-electron waves for which the exchange splitting would be smaller ($\approx$0.1 eV). This fact accounts for the strong suppression of transverse spin momentum mentioned in the preceding text.

This suppression makes credible the *spin-channel model* of electron transport (Valet and Fert, 1993). Consider, for example, the layered submicron metallic pillar joining two nonmagnetic semi-infinite conductors N_L and N_R shown in Figure 1. It is rotated 90° so that the deposition plane is oriented vertically. The pillar includes left (F_L) and right (F_R) magnets separated by a very thin nonmagnetic metallic spacer N. The cross section in the plane parallel to the substrate is an ellipse with dimensions typically 100 × 60 nm.

Of interest is electron transport through this pillar between the voltages $V = V_1$ deep within a relatively bulky electric lead on the left and another voltage $V = 0$ deep within a similarly bulky lead on the right. In metals a convenient

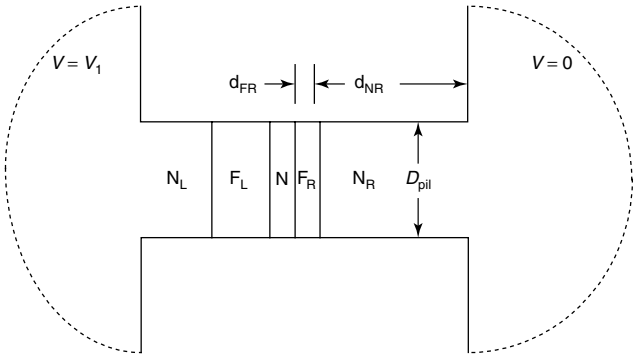

Figure 1. Magnetic multilayer pillar laid sideways. N: normal metal; F: ferromagnet; L: left; R: right.

measure of spin relaxation is the characteristic so-called spin 'diffusion' (relaxation, really) length (λ_N or λ_F) measuring the *spatial* decay of polarization $\langle\sigma_z\rangle$ proportional to the function $\exp(-x/\lambda_N)$ or $\exp(-x/\lambda_F)$ (Valet and Fert, 1993).

The dimensions of experimental pillars often approach the condition that they are too small for relaxation to be of consequence. The thickness of each sublayer component must be less than the corresponding diffusion length. Sufficient such conditions for the pillar of Figure 1 are

$$d_{NL}, d_{NR} \ll \lambda_N; \quad d_{FL}, d_{FR} \ll \lambda_F \tag{1}$$

If satisfied, they make valid the effective resistive circuit of Figure 2 featuring four channel resistors $R_{L\pm}$, $R_{R\pm}$. Our representation of spin relaxation in the external leads by means of the shorts shown in Figure 2 requires an opposite sort of condition, namely that dimensions of the leads are greater than $\lambda_{N,R}$. If one of these conditions is violated, the problem requires solution of a two-component diffusion equation (Valet and Fert, 1993).

2.2 Half-pillar resistors

We embrace the limits (1) and the spin-channel shorts shown in Figure 2. This will focus attention on the problem created by noncollinear spin-quantization axes. For the moment, we put aside the central 'junction box' appearing in the figure. One may decompose each of the four *half-pillar* unit-area channel resistors $R_{L\pm}$ and $R_{R\pm}$ into terms in series arising from two-channel bulk resistivity $\rho_\pm$, from two-channel unit-area interfacial resistance $r_\pm$, and from an end-effect term occurring at the pillar-lead connection. Thus, half-pillar unit-area resistances between either lead and the spacer (see Figure 1), with the subscripts R and L here elided, are

$$R_\pm = \rho_\pm d_F + 2r_\pm + \rho_N\left(2d_N + \frac{\pi D_{pil}}{2}\right) \tag{2}$$

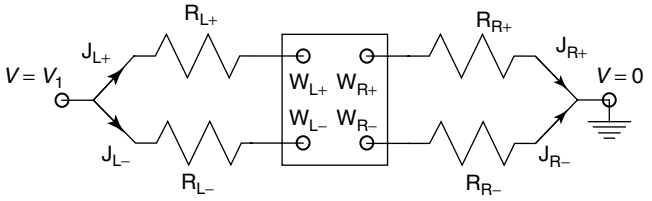

Figure 2. Effective two-channel circuit for the pillar of Figure 1 containing an N/F/N multilayer. Properties of the central 'junction box' are key to electron transport when $\mathbf{M}_L$ and $\mathbf{M}_R$ are not collinear.

where d_F and d_N are layer thicknesses and D_{pil} is the pillar diameter. (Section 3.2 justifies our neglect of bulk resistivity *within* the central spacer.) The final term $\pi\rho_N D_{pil}/2$ is due to the lead-to-pillar contact, approximated by half of a *constriction* resistance ρ_N/D_{pil} derived long ago by J. C. Maxwell. (The conducting constriction in Maxwell's case joins two semi-infinite conductors of homogeneous resistivity.)

A group at Michigan State University (Bass and Pratt, 2001) systematically measured collinear magnetoresistance of magnetron-sputtered periodic N/F/N/F/N . . . multilayers, numbering as many as 40 periods, at 4.2 K. This study established values of the specific resistance parameters appearing in equation (2). These values, together with independent values of ρ_N and spin diffusion distances λ_F and λ_N occurring in conditions (1) appear in the table below.

The low-temperature resistivity of Cu and Ag varies with sputtering conditions but is typically about three times its 300 K value given in the table. Sometimes the magnet F_L is part of the substrate; then, in the limiting cases $\lambda_{FL} \ll D_{pil}$ and $\lambda_{FL} \gg D_{pil}$, this equation for L is replaced by the

Table 1. Transport parameters for multilayers composed of sputtered Co, Cu, and Ag.

Parameter (K)	Units	Co/Cu	Co/Ag
$\rho_N(300)$	nΩm	17	16
$\lambda_F(4.2)$	nm	50	50
$\lambda_N(4.2,\ 300)$	nm	1500, 350	
From collinear GMR experiments (Bass and Pratt, 2001) at 4.2 K

estimate

$$R_{L\pm} = r_{\pm} + \rho_{\pm} \cdot \min(\Lambda_{sf}, \pi D_{pil}/4) \tag{3}$$

where D_{pil} is the diameter of the pillar. (See **Spin-transfer in High Magnetic Fields and Single Magnetic Layer Nanopillars, Volume 5** for effects of more general conditions of spin relaxation.)

3 EFFECTIVE CIRCUIT FOR A NONCOLLINEAR ALL-METALLIC PILLAR

We now address the crucial properties of the spacer N represented by the junction box in Figure 2.

3.1 Spin polarization in a rotated reference frame

The term *spin-accumulation*, or spin-polarization density, in a *normal* metal refers to the expectation value $\langle \sigma_z \rangle$ of σ_z for the electrons occupying a unit volume. Of course, its value depends on the orientation of the quantization axis ζ. How it transforms in a spacer under coordinate-axis rotation is crucial to electron transport in noncollinear magnetic multilayers.

Consider a total of $2n_0$ electrons occupying only given numbers $n_0 + n_{\pm}$ of *pure* eigenstates $|\pm\rangle$ of $\sigma_z = \pm 1$, respectively, in the unprimed spin-quantization frame. By definition, the spin accumulation in a normal metal n is

$$\Delta n \equiv \langle \sigma_z \rangle = n_+ - n_- \tag{4}$$

with $n_+ = n_-$ to preserve neutrality of charge density which occurs in the absence of significant electrostatic capacitance. Consider the primed frame, whose z' axis lies in the xy-plane at an angle θ from the z axis. The same electrons have the new spin accumulation

$$\Delta n' \equiv \langle \sigma_{z'} \rangle = n'_+ - n'_- \tag{5}$$

where $n_0 + n'_{\pm}$ is the expectation value of $\sigma_{z'}$. Applying the square-law of probability, n'_+ is obtained from the first column of the spin rotation matrix (Sakurai, 1985)

$$\langle \sigma | \sigma' \rangle = \begin{pmatrix} \cos(\theta/2) & \sin(\theta/2) \\ -\sin(\theta/2) & \cos(\theta/2) \end{pmatrix} \tag{6}$$

The result is

$$n'_+ = n_+ \cos^2 \frac{\theta}{2} + n_- \sin^2 \frac{\theta}{2} \tag{7}$$

From the second column of equation (6), one finds

$$n'_- = n_+ \sin^2 \frac{\theta}{2} + n_- \cos^2 \frac{\theta}{2} \tag{8}$$

After substitution of equations (7), (8), and (4), equation (5) reduces to

$$\Delta n' = \Delta n \cos\theta \tag{9}$$

Application of this equation requires caution because it involves no interaction, no physical change in the condition of the system during the transformation. The spins states remain pure eigenstates $|\pm\rangle$ of σ_z in the unprimed frame throughout.

3.2 Spin-dependent electron distribution within the spacer

Our treatment of noncollinear spin-dependent transport here neglects all scattering within the spacer. It is equivalent to special cases of the computational drift-diffusion approach of M. Stiles and coworkers (Stiles and Miltat, 2005). It is also a special case of independent circuit theory by Wainthal, Myers, Brouer and Ralph (2000). It differs from a formulation leading to a general circuit theory (See Brataas, Nazarov and Bauer, 2000 and Section 6.2 of Brataas, Bauer and Kelly, 2006) by taking into account explicitly the momentum dependence of spin state within a spacer free of scatterers. Our theory is appropriate to many experiments in which the copper spacer thickness is much smaller than the mean free path Λ due to phonon scattering of about 40 nm at 300 K. At much lower temperatures, where the parameter values in Table 1 were determined, defect scattering dominates Λ which may be three times greater still. Nonetheless, in the appropriate limit, the general theory (Brataas, Bauer and Kelly, 2006) reduces to our connection formulas given in the subsequent text (Bauer, G.E.W. private communication).

Figure 3 indicates a left ferromagnet F_L, having spontaneous magnetization $\mathbf{M}_L = -M_L\mathbf{l}$, separated from a right ferromagnet F_R, having spontaneous magnetization $\mathbf{M}_R = -M_R\mathbf{r}$, by a nonmagnetic metal N. Here, $\mathbf{l}$ and $\mathbf{r}$ are unit vectors forming the general mutual angle $\theta = \cos^{-1}(\mathbf{l} \cdot \mathbf{r})$. We assume the presence of steady state spin-dependent currents within each ferromagnet The proximity of two different ferromagnetic polarization axes $\mathbf{l}$ and $\mathbf{r}$ implies the absence of any single axis of spin polarization appropriate to electrons within N. To deal with this situation, we describe in the subsequent text the statistically steady electron state within N that is consistent with the channel currents and potentials of the ferromagnets.

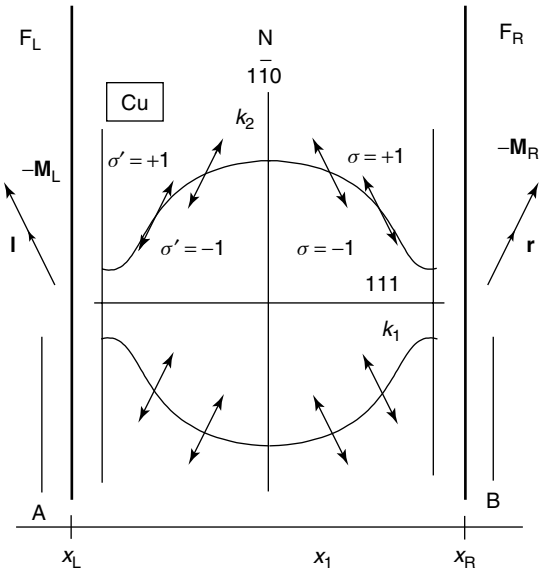

Figure 3. Notations for a metallic trilayer including ferromagnetic layers F_L with magnetization vector $\mathbf{M}_L$ at left and F_R with magnetization $\mathbf{M}_R$ at right, separated by a nonmagnetic spacer N. Shown schematically is a $11\bar{2}$-section of the Fermi surface for a Cu spacer with 111-axis normal to the layer plane. Arrows on the surface depict spin-polarization axes described in the text. The right (left) half of the Fermi surface is polarized parallel to the moment axis of the left (right) magnet.

We distinguish alternative **l**- and **r**- quantization axes for Pauli spin with operators σ_l and σ_r satisfying eigenstate equations $\sigma_l|\mathrm{L},\sigma\rangle = \sigma|\mathrm{L},\sigma\rangle$ ($\sigma = \pm 1$, sometimes abbreviated as $\sigma = \pm$) and $\sigma_r|\mathrm{R},\sigma'\rangle = \sigma'|\mathrm{R},\sigma'\rangle$ ($\sigma' = \pm 1$, or $\pm$). The spin states satisfy

$$\langle i,\sigma|i,\sigma''\rangle = \delta_{\sigma,\sigma''} \quad (i = \mathrm{L},\mathrm{R}) \tag{10}$$

and the plane spin rotation transformation

$$\langle \mathrm{L},\sigma|\mathrm{R},\sigma'\rangle = \begin{pmatrix} \cos(\theta/2) & -\sin(\theta/2) \\ \sin(\theta/2) & \cos(\theta/2) \end{pmatrix} \tag{11}$$

in equation (6).

Total absences of exchange coupling and scattering within N are assumed. Whatever atomic-scale subregion within the spacer, adjoining F_L or F_R, contains significant decaying exchange, or any interface-related scattering centers which may be present, is considered to belong to that magnetic region ($x_1 < x_L$ or $x_1 > x_R$) rather than to N.

Note, however, that any electron within N ($x_L < x_1 < x_R$) moving *rightward*, thus satisfying $v_1(\mathbf{k}) > 0$ and represented by decoration with the symbol $\rightarrow$, last *either* passed through (transmitted), *or* backscattered from, the *left* (F_L/N) interface. If transmitted, its final polarization is clearly $|\mathrm{L},+\rangle$ or $|\mathrm{L},-\rangle$ according to the two-channel model of spin-polarized current flowing in F_L. If backscattered, the electron spin has *the single polarization* $|\mathrm{L},-\rangle$ under an assumed condition of *perfect majority-spin transmission* (PMST; see in the subsequent text.) through the interface. Therefore, a rightward-moving electron [$\rightarrow$,with $v_1(\mathbf{k}) > 0$] has pure spin polarization $|\mathrm{L},+\rangle$ or $|\mathrm{L},-\rangle$, with no mixing that would describe a spin tilt away from this quantization axis. Similarly, a leftward-moving electron [$\leftarrow$,with $v_1(\mathbf{k}) < 0$] has only pure spin polarization $|\mathrm{R},+\rangle$ or $|\mathrm{R},-\rangle$. This scheme for the case of a 111-textured multilayer is illustrated in the $11\bar{2}$-section of the copper Fermi surface sketched within Figure 3.

The PMST condition is supported very well by the very small experimental values of interfacial resistance r_+ for Co/Cu and Co/Ag interfaces seen in Table 1 of Section 2.2. (They are one order of magnitude smaller than the respective r_-. They are consistent with a mean reflection coefficient of $\approx$5%.) If this were 0% then reflected electrons could have only the minority-spin orientation and the polarization scheme in Figure 3 would be exact. Therefore, for pillars composed of Co and Cu or Ag this electron distribution is well justified.

Why do the majority-spin electrons reflect so weakly? The answer lies in the following peculiarity of ferromagnetic electron structure: In experimental sputtered films, the metals Co, Ni, and Cu all have face-centered cubic (fcc) structure. As atomic number A increases in the sequence Co($A = 27$), Ni(28), Cu(29), the majority-spin electrons have the constant configuration $3d^5s^1$. Then in this range of A, each additional electron enters the minority band (Kübler, 2000). Consequently, the majority-spin energy bands differ very little. As indicated in the schematic cross section shown in Figure 3, the majority-spin Fermi surface for Co (and Ni) differs from a free-electron sphere mainly by the presence of small 'necks' which lie along 111-axes and join the surface to the Brillouin-zone boundary. The diameter of the neck increases a little in passing to Cu, but the remainder of the Fermi surface hardly changes. A majority-spin electron incident onto such an interface feels little change in potential. For this reason, majority-spin electrons reflect weakly at Co/Cu and Ni/Cu interfaces. Results of first-principle numerical computations (Xia *et al*., 2002) support this qualitative conclusion.

3.3 Connecting channels across a spacer without scatterers

Spin-channel currents through a magnet are driven by a *chemical potential* in addition to the ordinary electrostatic potential. To explain this fact, consider $T = 0\,\mathrm{K}$. Begin at thermal equilibrium with fully occupied states in the spacer having energy $\varepsilon \leq \varepsilon_{F0}$, with ε_{F0} the Fermi level. Then

apply the electrostatic voltage V to the spacer. Clearly, the new Fermi level for each σ is $\varepsilon_F \to \varepsilon_{F0} - eV$ and the particle potential $-eV$ provides impetus to drive electrons away from (or attract them to) the spacer. Suppose that some nonequilibrium process now adds the number n_σ of electrons per unit volume to the channel $\sigma = \pm$ within the spacer. Because of the exclusion principle, the Fermi level must rise in first-order approximation by the amount n_σ/n_F, where $2n_F$ is the electron density per unit energy and volume at $\varepsilon = \varepsilon_{F0}$, in order to make room for the added electrons. Clearly, now the Fermi level is spin-dependent and given by $\varepsilon_{F,\sigma} = \varepsilon_{F0} - eV + (n_\sigma/n_F)$. Surely, the 'chemical' voltage $-n_\sigma/en_F$ is able to drive a channel current just as well as the equivalent amount of electric voltage V. It follows that transport in spin channels requires augmenting the electric voltage to form the total *electrochemical* voltage defined by

$$W_\sigma = V - \frac{n_\sigma}{en_F} \tag{12}$$

One must hasten to add that in the absence of appreciable electrostatic capacitance, which we assume, charge neutrality is preserved. Thus, one has the condition $n_+ = -n_-$. It is easy to see that this expression for W_σ is correct at $T > 0\,\mathrm{K}$ as long as kT is small compared to the width of the energy band.

So now we know that electric current density J_σ in our simplified (see Section 2.2) half-pillar spin channel $\sigma(= \pm)$ must be written $J_\sigma = W_\sigma/R_\sigma$, where R_σ is the unit-area resistance. According to the laws of electric circuits, the ordinary *electric* voltage $V = (W_+ + W_-)/2$ and true *electric* current $J = J_+ + J_-$ must be continuous everywhere, and in particular across the central normal-metal spacer N in Figure 1. But we need four continuity relations altogether, so we must find two more in order to solve the complete circuit in Figure 2. We attach the subscripts L and R to specify values for every quantity *evaluated within the spacer*, using the left and right spin-coordinate axes, respectively. Thus, left and right so-called *spin-accumulation* or polarization densities are

$$\Delta n_L \equiv n_{L,+} - n_{L,-} \text{ and } \Delta n_R \equiv n_{R,+} - n_{R,-} \tag{13}$$

Accordingly, we have

$$\Delta W_L \equiv W_{L,+} - W_{L,-} = -\left(\frac{\Delta n_L}{en_F}\right) \text{ and}$$
$$\Delta W_R = -\left(\frac{\Delta n_R}{en_F}\right) \tag{14}$$

Finding two relations connecting ΔW_R and ΔJ_R to ΔW_L and ΔJ_L will suffice, together with continuity of V and J, to provide the four relations needed to solve the circuit of Figure 2.

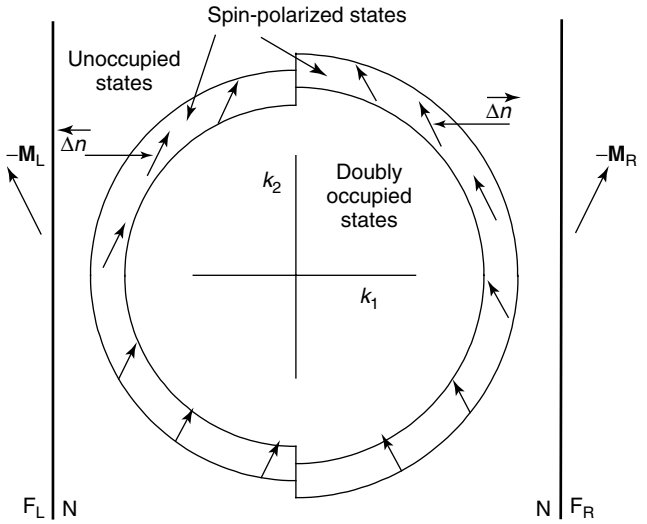

Figure 4. Scheme of **k**-dependent spin accumulation within the normal spacer N. It illustrates the parameterization of the nonequilibrium spin polarization of the Bloch states in a metallic spacer having a spherical Fermi surface.

To proceed further, we need to parameterize the spin-polarization scheme shown in Figure 4. For simplicity, the Fermi surface is spherical. This figure indicates that the spin polarization of electrons within N is concentrated within two hemispherical shells located on the Fermi surface and marked with scalar *partial spin accumulations* $\overleftarrow{\Delta n}$ and $\overrightarrow{\Delta n}$. The thicknesses of these shells are infinitesimal for linear transport. The left-(right-) arrow above the symbol $\overleftarrow{\Delta n}$ ($\overrightarrow{\Delta n}$) means that the electrons are moving leftward(rightward), $v_1 < (>)0$. In accordance with our discussion of the PMST condition connected with Figure 3, the polarization axis for $\overleftarrow{\Delta n}(\overrightarrow{\Delta n})$ is $-\mathbf{M}_R(-\mathbf{M}_L)$. The electron states outside of these shells are either doubly occupied or empty and therefore unpolarized in both cases.

To evaluate Δn_L, note that the shell marked $\overrightarrow{\Delta n}$ is already polarized along axis $-\mathbf{M}_L$ so it contributes to the total as it stands. But the one marked $\overleftarrow{\Delta n}$ is polarized along the other axis $-\mathbf{M}_R$ so its contribution must be projected upon the axis $-\mathbf{M}_L$. Therefore, one has from equation (9)

$$\Delta n_L = \overrightarrow{\Delta n} + \overleftarrow{\Delta n}\cos\theta \tag{15}$$

One then has from equation (14), and similarly using $\Delta n_R = \overleftarrow{\Delta n} + \overrightarrow{\Delta n}\cos\theta$

$$\Delta W_L = -\frac{(\overrightarrow{\Delta n} + \overleftarrow{\Delta n}\cos\theta)}{en_F},$$
$$\Delta W_R = -\frac{(\overleftarrow{\Delta n} + \overrightarrow{\Delta n}\cos\theta)}{en_F} \tag{16}$$

Evaluation of the current difference $\Delta J_{\mathrm{L}} \equiv J_{\mathrm{L}+} - J_{\mathrm{L}-}$ is similar, except that to obtain current, one must weight the terms $\overleftarrow{\Delta n}(\overrightarrow{\Delta n})$ in equation (15) with $\mp e\overline{v}$, where $\overline{v}$ is the mean of $v_1(\mathbf{k})$ over the right hemisphere of the Fermi surface. (Similarly for ΔJ_{R}.) Thus the current differences are

$$\Delta J_{\mathrm{L}} = e\overline{v}(\overleftarrow{\Delta n}\cos\theta - \overrightarrow{\Delta n}), \quad \Delta J_{\mathrm{R}} = e\overline{v}(\overleftarrow{\Delta n} - \overrightarrow{\Delta n}\cos\theta) \tag{17}$$

From the four equations (16) and (17), one may eliminate the two variables $\overleftarrow{\Delta n}$, $\overrightarrow{\Delta n}$ to find the two desired connection equations:

$$\Delta J_{\mathrm{R}} = \left[\Delta J_{\mathrm{L}}(1+\cos^2\theta) - G\Delta W_{\mathrm{L}}\sin^2\theta\right]/2\cos\theta \tag{18}$$

$$\Delta W_{\mathrm{R}} = \left[-G^{-1}\Delta J_{\mathrm{L}}\sin^2\theta + \Delta W_{\mathrm{L}}(1+\cos^2\theta)\right]/2\cos\theta \tag{19}$$

where the single spacer-material parameter required is

$$G = \frac{e^2 n_{\mathrm{F}}\overline{v}}{2} \tag{20}$$

These equations are verifiable by substitution of equations (16) and (17).

Since the mean of v_1^2 equals $v_{\mathrm{F}}^2/3$ where v_{F} is the Fermi velocity of an assumed spherical Fermi surface of the spacer composition, the rms relation $\overline{v} \approx v_{\mathrm{F}}/3^{1/2}$ may be used to estimate $\overline{v}$. For a parabolic band this formula then becomes

$$G = \frac{e^2 k_{\mathrm{F}}^2}{3^{1/2}\pi h} \tag{21}$$

which is $2/3^{1/2}$ times the Sharvin ballistic conductance G_{Sh} (2 spins) per unit area of a constriction whose diameter is smaller in order of magnitude than the mean free path. (Note, however, that the Sharvin ballistic resistance *phenomenon,* which occurs when the aperture *diameter* is smaller than Λ, plays no role in the present theory because all our potentials and currents are independent of x_1 within the spacer region N.) Equation (21) gives $G = 1.32 \times 10^{15}\ \Omega^{-1}\mathrm{m}^{-2}$ for a free-electron gas having the electron density of Cu.

The crucial role of equation (15) in this derivation must be understood. Validity of the two-channel model in a half-pillar does not require the spins within the adjoining spacer to occupy pure eigenstates of σ_ζ where ζ is parallel to $\mathbf{M}$ of the ferromagnet. One *does* need a correct electron distribution within the spacer as parameterized by our model for the partial spin accumulations $\overleftarrow{\Delta n}$ and $\overrightarrow{\Delta n}$ indicated in Figure 4. From these, one needs to evaluate only the *expectation* values of the properly evaluated *expectation* values of the accumulations to evaluate $\Delta W_{\mathrm{L,R}}$ and $\Delta J_{\mathrm{L,R}}$. The fact that not all spins are parallel to the same axis $\mathbf{l}$ or $\mathbf{r}$ does not matter.

The connection formulas (18) and (19) may reasonably be applied to Co, Ni, and alloys that lie on the negative-slope side of the Neel–Slater–Pauling curve (Kübler, 2000) in which the majority-spin 3d-band is fully occupied. For then the majority-spin electrons at the Fermi level belong to the sp-band and therefore approach the condition of 100% transparency assumed in the derivation in the preceding text. In particular, these formulas should not be applied when an electrode is composed of Fe. Nor do they apply to the case $\Lambda \ll$ (spacer thickness) treated elsewhere (Barnaś *et al.*, 2005).

4 CURRENT-DRIVEN PSEUDOTORQUE

Our object is to calculate the electric resistance and current-driven torque for a pillar with noncollinear moments. The important thing is to solve the circuit equations for the noncollinear condition considered in Section 3. As illustrated in Section 5, the connection formulas (18) and (19) are key to this solution. With this solution in hand, the resistance will be simply

$$R(\theta) = \frac{V}{(J_{\mathrm{L},+} + J_{\mathrm{L},-})} \text{ or } = \frac{V}{(J_{\mathrm{R},+} + J_{\mathrm{R},-})} \tag{22}$$

But the current-driven torque needs the detailed discussion given in the present section.

4.1 Torque mechanism

We explain first how the exchange-reaction torque created by scattering of preferentially polarized electrons incident from a normal metal onto a ferromagnet concentrates on the magnetization located within a distance equal to $d_{\mathrm{impact}} \approx 4$ atomic layers of the interface.

Figure 5 depicts schematically the local spin vector of the stationary-state wave function for an electron incident rightward onto an N/F interface located at position $\xi \equiv x_1 = 0$. (The spin-coordinate axes η, ζ in Figure 5 have no special relation to the position coordinates x_2, x_3 of the

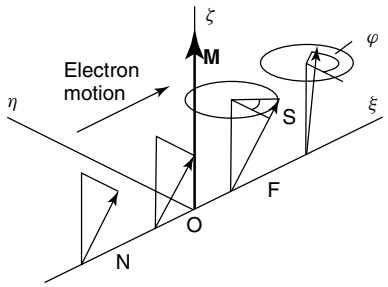

Figure 5. Illustration of spin precession for an electron passing from a nonmagnetic metal ($\xi < 0$) into a ferromagnetic metal ($\xi > 0$).

pillar illustrated in Figure 1.) Within the region N, the local expectation of vector spin operator $\mathbf{s} = \hbar\sigma/2$ for the incident wave is a general constant. Dynamical reaction to the spin momentum scattered by the magnet causes a torque on **M**. Under the PMST assumption in Section 3.2 only minority spin $\sigma = -$ can scatter backwards into N. (This reflected wave is not indicated in Figure 5.) But this *reflected* momentum is collinear with **M**, therefore its reaction does not contribute torque.

The local expectation of **s** for the wave component *transmitting* into the ferromagnet ($\xi > 0$) has an azimuthal angle with respect to the moment **M** of F given by

$$\varphi(\xi) = \varphi(0) + (k_{\xi+} - k_{\xi-})\xi, (\xi > 0) \tag{23}$$

where $k_{\xi\pm}$ are the normal components of electron wave vectors at $\varepsilon = \varepsilon_F$ for $\sigma = +$ and $\sigma = -$. (For graphical simplicity, Figure 5 shows $\mathbf{M}\|\zeta$, but actually **M** may have any direction.) For a given energy, the two values of $k_{\xi\pm}(k_\eta, k_\zeta)$ depend on the conserved transverse momentum components $\hbar(k_\eta, k_\zeta)$ and differ because of internal exchange.

In diffusive metallic transport, the wave vectors of all incident electrons having a given **s** lie very near all parts of the Fermi surface. Therefore the quantity $k_{\xi+} - k_{\xi-}$ varies over a great range. It follows that the averages of $s_\xi \propto \cos\varphi$ and $s_\eta \propto \sin\varphi$ at a given plane ξ approach 0 within an impact depth $\xi = d_{\text{impact}}$ of a few atomic layers (Xia *et al.*, 2002; Stiles and Zangwill, 2002). If the scale of micromagnetic homogeneity treated in the continuum representation with the Landau–Lifshitz equations is greater than this impact depth, as for the monodomain treated in Section 6, the reaction of this precession communicates to the magnet the net of the **s** components transverse to **M** of all of the electrons passing through the I/F interface into the magnet F. It follows also that the reactive momentum impulse given to F acts essentially at the interface and lies within the **M–s** plane determined by the incident electrons.

Crucial is the principle of conservation of spin momentum which follows from absence of spin operators in the *N*-electron Hamiltonian for a solid:

$$\mathcal{H} = \sum_i \frac{\mathbf{p}_i^2}{2m} + \sum_{i<j} \frac{e^2}{|\mathbf{r}_i - \mathbf{r}_j|} - \sum_{i,l} \frac{e^2 Z_l}{|\mathbf{r}_i - \mathbf{R}_l|} \tag{24}$$

The first of three terms above is kinetic energy with $\mathbf{p}_i$ the electron momentum operator, the second is coulomb interaction between electrons at positions $\mathbf{r}_{i,j}$, and the third is the coulomb interaction between electron i and atomic nucleus l carrying charge Z_l at fixed position $\mathbf{R}_l$. (Internal exchange coupling responsible for the formation of spontaneous magnetization of a ferromagnet arises from the antisymmetry principle even though spin operators are absent from $\mathcal{H}$.)

Note that we neglect the small spin-orbit effect. Spin-orbit coupling, in combination with defect scattering, determines the spin relaxation lengths λ_N and λ_F tabulated in Table 1. Its neglect is valid in the following derivation of torque from currents because λ_N, λ_F, and Λ are much greater than d_{impact} (see Section 4.1).

4.2 A general torque relation

Spin-momentum conservation causes the corresponding effective vectorial surface-torque densities $\mathbf{T}_L$ and $\mathbf{T}_R$ (with $\mathbf{l}\cdot\mathbf{T}_L = 0$ and $\mathbf{r}\cdot\mathbf{T}_R = 0$) to satisfy the vector equation

$$\mathbf{T}_L + \mathbf{T}_R = K_R\mathbf{r} - K_L\mathbf{l} \tag{25}$$

Here

$$K_n \equiv \hbar(J_{n,-} - J_{n,+})/2e \tag{26}$$

is the rightward flowing *spin-momentum* current (or spin current for brevity) density within magnet n(=L or R), $-e$ is the electron charge and $J_{n\pm}$ is the *electric* current density flowing in the majority- or minority-spin channel of the respective magnet in the two-channel model of perpendicular magnetoresistance. By convention, both charge and momentum *current* directions are reckoned positive along the $+x_1$ direction in Figure 3. (These densities are assumed independent of x_2 and x_3.) Accordingly, the right-hand side of equation (25) represents the net rate of spin momentum flowing into the region enclosed by two geometric planes A and B (see Figure 3) located inside the magnets at the distance d_{impact} from the F/N interfaces; the left side gives the consequent sum of macroscopic torques concentrated on the magnets at these interfaces. The great strength of the internal exchange stiffness within a pillar device insures that this torque is conveyed to their entire thickness as a whole.

As explained in the preceding text, the coplanar orientation of $\mathbf{T}_L(t)$ and $\mathbf{T}_R(t)$ with the moments $\mathbf{M}_L$ and $\mathbf{M}_R$ displayed in Figure 6 are general. Their scalar magnitudes are obtained by forming the scalar products of equation (25) alternatively with $\mathbf{M}_L$ and $\mathbf{M}_R$:

$$T_L = \frac{(K_L\cos\theta - K_R)}{\sin\theta} \tag{27}$$

$$T_R = \frac{(K_R\cos\theta - K_L)}{\sin\theta} \tag{28}$$

where the sign convention for the scalars is indicated in the Figure 6.

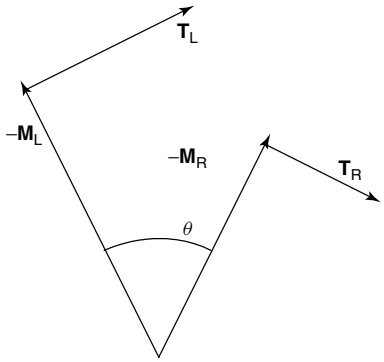

Figure 6. The torque vectors $\mathbf{T}_L$ and $\mathbf{T}_R$ lie within the plane containing the instantaneous magnetization vectors.

Equations (26)–(28) are key to current-driven torque for, given the spin-channel currents obtained by solving the effective circuit, these equations predict the corresponding torques to be included in the Landau–Lifshitz equations used later to treat domain dynamics and switching. Thus both questions of conductance (see equation (22)) and torque are reduced to solution of the effective circuit equations introduced Section 3 (see also **Theory of Spin-transfer Torque, Volume 2**).

5 MAGNETORESISTANCE AND CURRENT-DRIVEN TORQUE OF A SYMMETRIC PILLAR

5.1 The magnetoresistance

The two relations (18) and (19) provide the connection across spacers needed to complete the effective circuit Kirchoff equations for angular dependence of perpendicular magnetoresistance. A method of solution for broad classes of pillars, with significant complication due to spin relaxation, are published (Manchon and Slonczewski, 2006). To take a simple example, the magnetoelectronics of a trilayer $F_L/N/F_R$ is described by the circuit diagram of Figure 7 in the special

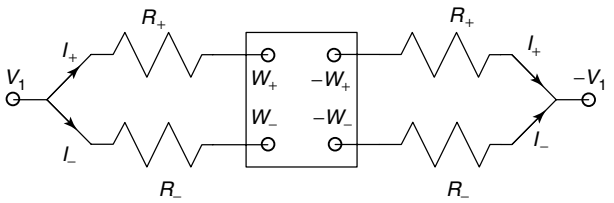

Figure 7. Effective circuit for the trilayer when magnets F_L and F_R are equal. $R_\pm$ are the channel resistances of each magnet and lead combination. Equations (18) and (19) connect the currents and voltages across the spacer and equation (32) gives the total resistance.

case that F_L and F_R have identical properties and thicknesses and spin relaxation within the magnets can be neglected. The channel resistances $R_\pm$ should include both the bulk and interfacial contributions given in equation (2).

To take advantage of the resulting odd voltage symmetry and even current symmetry, electric voltage V_1 is applied to the left contact and $-V_1$ to the right. Then symmetry permits omission of the subscripts L and R and dictates the disposition of current densities, $J_\pm \equiv J_{L\pm} = J_{R\pm}$, voltages $W_\pm \equiv W_{L\pm} = -W_{R\pm}$, shown in Figure 7, as well as the relations $\Delta J \equiv J_+ - J_-$, $\Delta J_R = \Delta J_L$ and $\Delta W_R = -\Delta W_L$. ($J_\pm$ is shown as $I_\pm$ in Figure 7.) The total unit-area resistance is

$$R = \frac{2V_1}{(J_+ + J_-)} \tag{29}$$

Our neglect of spacer resistance means $V_L = V_R = 0$, implying $W_+ = -W_-$ according to equation (12).

Each relation (18) and (19) now reduces to the single independent equation

$$(J_+ - J_-)(1 - \cos\theta)^2 = G(W_+ - W_-)\sin^2\theta \tag{30}$$

Kirchoff's laws give the two relations

$$W_\pm = V_1 - R_\pm J_\pm \tag{31}$$

Simple elimination between equations (29–31) gives the result

$$R(\theta) = \frac{(R_+ + R_-)\sin^2(\theta/2) + 2GR_+R_-\cos^2(\theta/2)}{2\sin^2(\theta/2) + G(R_+ + R_-)\cos^2(\theta/2)} \tag{32}$$

Experimental data is usefully reduced to the dimensionless variable

$$r = \frac{R(\theta) - R(0)}{R(\pi) - R(0)} \tag{33}$$

Interpretation of experiments sometimes centers on deviation of the r data from linearity with respect to the variable $\cos^2(\theta/2)$ as measured by the parameter χ in the formula

$$r = \frac{1 - \cos^2(\theta/2)}{1 + \chi\cos^2(\theta/2)} \tag{34}$$

Figure 8 illustrates this relation. In these terms, the formulas (32) and (33) combine to give

$$\chi = \frac{1}{2}G(R_+ + R_-) - 1 \quad (> -1) \tag{35}$$

Experimental values of χ thus far are positive, including those for trilayers FeCo/Cu/FeCo and NiFe/Cu/NiFe having

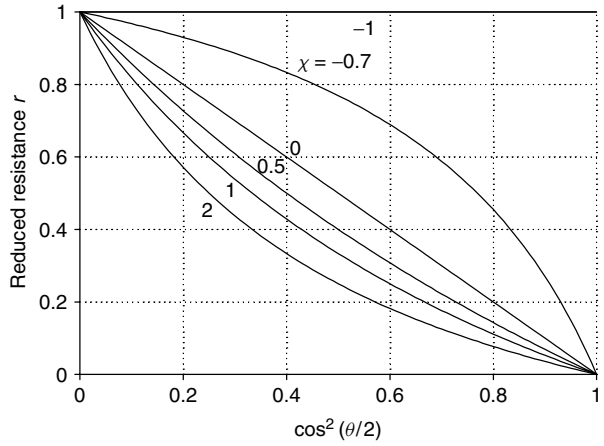

Figure 8. Angular dependence of reduced magnetoresistance on angle θ between magnetic moments defined by equation (33), according to equations (34) and (35).

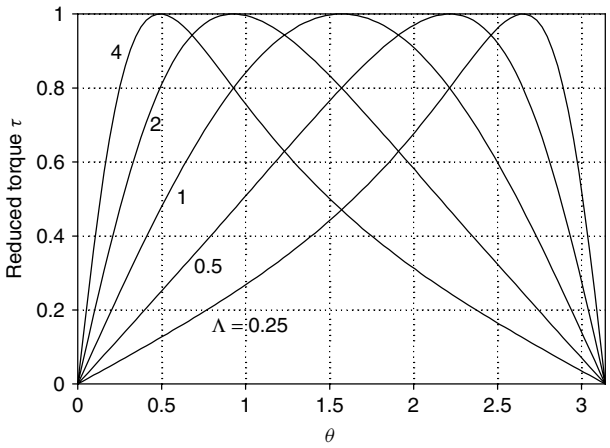

Figure 9. Dependence of reduced torque on angle θ for a trilayer with identical ferromagnetic sublayers. The parameter Λ is given by equation (37).

equal magnets. Application of the present theory to these experiments would require G to be about half of our expected $1.4 \times 10^{15}\ \Omega^{-1}\,\mathrm{m}^{-2}$ (Bass, J. private communication). However, the present theory takes no account of the antiferromagnetic and superconducting connecting layers used in the experiments. In addition, since the magnets are composed of alloys that include Fe, we do not know how well they satisfy the condition of negligible majority-spin interfacial reflection assumed by the theory (see Section 3.2) (see also **Enhanced Magnetoresistance, Volume 1**).

5.2 Torques on a symmetric trilayer

Specializing now to our illustrative case of two identical magnets in the preceding text (see Figure 7), application of the relations (30) and (31) reduces equation (28) to the new torque relation for either magnet:

$$T = \frac{\hbar J P_\mathrm{r} \Lambda \tau(\theta)}{4e} \tag{36}$$

with

$$P_\mathrm{r} = \frac{(R_- - R_+)}{(R_+ + R_-)},\ \ \Lambda = \left[\frac{G(R_+ + R_-)}{2}\right]^{1/2} \tag{37}$$

and

$$\tau(\theta) = \frac{\sin\theta}{\Lambda \cos^2(\theta/2) + \Lambda^{-1}\sin^2(\theta/2)} \tag{38}$$

The latter reduced torque relation is plotted in Figure 9. Section 6 treats the effect of such a current-driven torque on the dynamic behavior of a monodomain using the Landau–Lifshitz equation.

6 DYNAMICS OF MAGNETIZATION DRIVEN BY CURRENT

Other chapters treat this subject in depth (see also **Magnetization Dynamics Including Thermal Fluctuations: Basic Phenomenology, Fast Remagnetization Processes and Transitions Over High-energy Barriers, Volume 2**, **Nonlinear Magnetization Dynamics in Nanomagnets, Volume 2**, **Microwave Generation in Magnetic Multilayers and Nanostructures, Volume 2**, **Spin Angular Momentum Transfer in Magnetoresistive Nanojunctions, Volume 5**, and **Microwave Excitations in Spin Momentum Transfer Devices, Volume 5**).

Our treatment here is minimal: For simplicity, consider a uniformly magnetized monodomain having uniaxial effective anisotropy field $H_\mathrm{u} = 2K_\mathrm{u}/M_\mathrm{s}$ where $K_\mathrm{u}\sin^2\theta$ is the total energy per unit volume, including material and shape terms. The free motion of the monodomain is a circular precession about the easy axis with constant θ and circular frequency $\omega = \gamma H_\mathrm{u}\cos\theta$.

In the presence of small damping (measured by the Gilbert coefficient α) and exchange (spin-transfer) torques, the time-dependence of the cone angle satisfies

$$\mathrm{d}\theta/\mathrm{d}t = \dot\theta_\mathrm{damp} + \dot\theta_\mathrm{exch} \quad \text{with} \tag{39}$$

$$\dot\theta_\mathrm{damp} = -\frac{1}{2}\gamma\alpha H_\mathrm{u}\sin 2\theta \quad \text{and} \tag{40}$$

$$\dot\theta_\mathrm{exch} = \frac{\gamma\hbar J g(\theta)}{eM_\mathrm{s}d_\mathrm{F}}\sin\theta \tag{41}$$

The latter three functions are plotted in Figure 10 for three values of dimensionless current I. (Units for all physical quantities are arbitrary.) The function $g(\theta)$ employed is

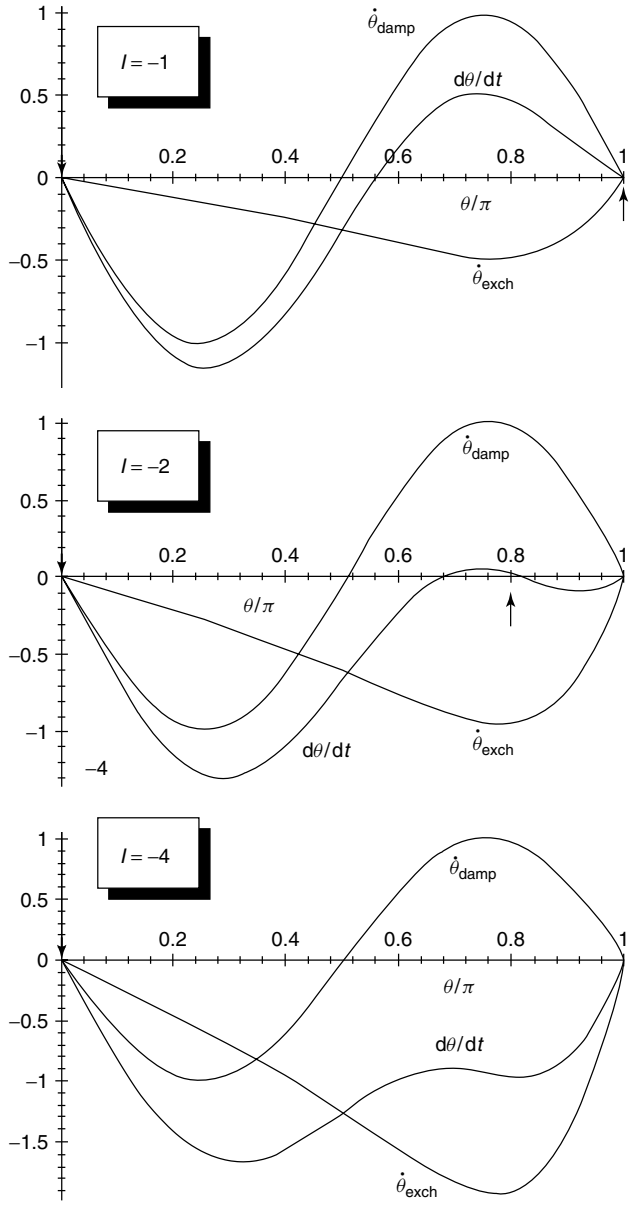

Figure 10. Instantaneous angular velocity versus angle θ of the precession cone for a uniaxial monodomain pillar magnet subject to viscous damping and three values of dimensionless current I, according to equation (39). Points of stable dynamic equilibrium are indicated by $\uparrow$ or $\downarrow$.

from an earlier theory (Slonczewski, 1996) and corresponds approximately to the symmetric pillar case $\Lambda = 0.4$ in Figure 9. Obvious conditions for the stability of any cone angle are $\mathrm{d}\theta/\mathrm{d}t = 0$ (equilibrium) and $\mathrm{d}[\mathrm{d}\theta/\mathrm{d}t]/\mathrm{d}\theta < 0$ (stability).

For $I = -1$, the remanent states $\theta = 0, \pi$ satisfy both conditions, but the intermediate equilibrium point $\theta = 0.56\pi$ is not stable. Therefore the current value $I = -1$ does not excite either of the two remanent states. In the time domain, consider a small initial fluctuation (e.g., thermal) $\theta = 0.95\pi$ from one remanent state. Then, integration of equation (39) shows that the current $I = -1$ permits the moment to relax exponentially to the nearby remanent state as illustrated by the top curve in Figure 11.

For $I = -2$, only two, ($\theta = 0,\ 0.79\pi$) of the four equilibrium states are stable. Therefore this value of current drives the moment out of the neighborhood of $\theta = \pi$ toward the first stable equilibrium $\theta = 0.79\pi$. (See Figure 11.) After it relaxes to this point, the moment continues to precess steadily at circular frequency $\omega = \gamma H_{\mathrm{u}} \cos 0.79\pi$ as long as the constant current $I = -2$ is maintained. If the current is subsequently turned off, then the moment falls to the nearer remanent state, $\theta = \pi$ in this case. This example illustrates the fact that the criterion $\mathrm{d}[\mathrm{d}\theta/\mathrm{d}t]/\mathrm{d}\theta = 0$ for instability threshold does not necessarily imply a full moment reversal.

For $I = -4$, only one state has a stable equilibrium, so that a complete reverse switch from $\theta = \pi^-$ to $\theta = 0$ occurs. (See Figure 11) Note that the current speeds up the relaxation to the final state.

Clearly, positive I of sufficient magnitude will switch in the forward direction from $\theta = 0^+$ to $\theta = \pi$. In this case ($I > 0$) it happens that a steady precessing state does not exist and the threshold current for instability of $\theta = 0$ does also cause a full switch. Thus for $H_{\mathrm{u}} > 0$, the possibility of a steady precessing state depends on the value of P and the sign of I. However, for $H_{\mathrm{u}} < 0$ there exists a range including both signs of I supporting a steady precession.

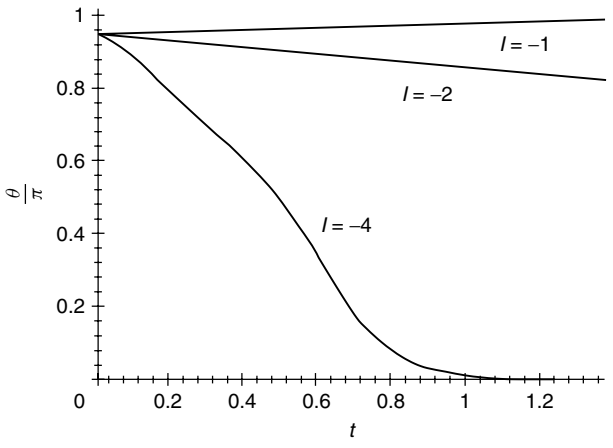

Figure 11. Dependence of precession-cone angle θ on time computed from equation (39) in arbitrary units. The initial state is $\theta = 0.95\pi$. The dimensionless current $I = -1$ causes no switch, $I = -2$ causes a partial switch to the precessing state $\theta = 0.79\pi$ and $I = -4$ causes a full switch to $\theta = 0$.

7 QUANTUM TUNNELING THEORY

Beginning with this section, we replace the metallic spacer in the magnetic multilayer with a tunneling barrier. A powerful way to treat tunneling is with the method of Bardeen, which uses Fermi's Golden Rule of time-dependent perturbation theory to describe the flow of electrons from one electrode to the other (Duke, 1969). It is best derived using the interaction picture for perturbation theory (Sakurai, 1985).

7.1 Interaction picture

Let ψ satisfy the Schroedinger wave equation

$$i\hbar\dot{\psi} = H\psi \tag{42}$$

for the one-particle Hamiltonian

$$H = -\frac{\left(\frac{\hbar \mathrm{d}}{\mathrm{d}x}\right)^2}{2m} + V(x) \tag{43}$$

in one dimension. Let $\phi_n(x)$ $(n = 0, 1, 2, \ldots)$ be a complete orthonormal set of basis functions. A general wave function may be expanded thus:

$$\psi = \sum_n C_n(t)\phi_n(x) \tag{44}$$

The matrix equivalent of the Schröedinger equation is found as usual to be

$$i\hbar\dot{C}_n = \Sigma_{n'} H_{n,n'} C_{n'} \tag{45}$$

with $\bullet \equiv \mathrm{d}/\mathrm{d}t$ and the matrix form of the Hamiltonian

$$H_{n,n'} = \langle \phi_n | H | \phi_{n'} \rangle \tag{46}$$

Now let H' be a small general perturbation:

$$H = H_0 + H' \tag{47}$$

Also, let $\lambda(x) \equiv \phi_0$ be a single initially occupied unperturbed state having vanishing energy: $H_0\lambda = 0$. Assume also $H'_{0,0} \equiv 0$. Each of the initially unoccupied remaining unperturbed states ϕ_n satisfy

$$(H_0 - \hbar\omega_n)\phi_n = 0 \ (n = 1, 2, \ldots) \tag{48}$$

with energy $\hbar\omega_n$. Use the interaction picture (Sakurai, 1985)

$$C_n = a_n(t)e^{-i\omega_n t} \tag{49}$$

with initial values $a_0(0) = 1$ and $a_n(0) = 0$ for $n = 1, 2, \ldots$ For $n \neq 0$, consider $H'_{n,n'}$, a_n, and ω_n to be first-order quantities. Upon substitution of equation (49), equation (45) reduces in first-order approximation to

$$\dot{a}_0 = 0, \quad \dot{a}_n = -iH'_{n,0}e^{i\omega_n t} \ \ (n = 1, 2 \ldots) \tag{50}$$

These are the linearized perturbation equations in the interaction picture. Our next goal is a special expression for $H'_{n,0}$ for the case of tunneling.

7.2 Tunneling rate

To describe tunneling from left to right, specialize to the case of V approaching the constant barrier height B within much of the barrier (see Figure 12). Let our $\lambda(x) \equiv \phi_0$ be one initial state having energy $E = 0$ which is localized within the *left* electrode by the potential $B + V_{\mathrm{L}}(x)$ where B is constant with $V_{\mathrm{L}} \leq 0$ for all x, and $V_{\mathrm{L}} = 0$ for $x > a$. Let the remaining ϕ_n be localized on the right of the barrier by the potential $B + V_{\mathrm{R}}(x)$ where $V_{\mathrm{R}} \leq 0$ for all x, and $V_{\mathrm{R}} = 0$ for $x < b$. The total potential of the system is $V = B + V_{\mathrm{L}}(x) + V_{\mathrm{R}}(x)$. The basic approximation of Bardeen is to neglect the nonorthogonality of λ to ϕ_n $(n = 1, 2, \ldots)$ due to the small wave function overlap within the barrier (Duke, 1969). (See Figure 12)

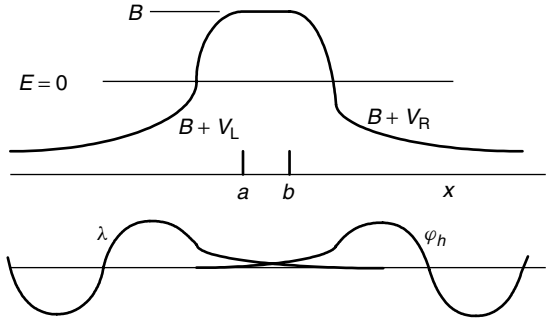

Figure 12. Potentials $V = B + V_{\mathrm{L}}$ and $V = B + V_{\mathrm{R}}$, plotted above, which define left $\lambda(x)$ and right $\phi_n(x)$ $n = 1, 2, 3, \ldots$ electrode basis functions, plotted schematically in the subsequent text, for Bardeen tunnel theory.

Equation (44) in the interaction picture for tunneling becomes

$$\psi = \lambda + \sum\nolimits_n a_n(t)\phi_n e^{-i\omega_n t} \tag{51}$$

The probability P_n for occupation of the state ϕ_n and its rate of increase $\dot{P}_n$ are

$$P_n = a_n^*\, a_n, \qquad \dot{P}_n = (\dot{a}_n^*\, a_n) + \text{c.c.} \tag{52}$$

Let's calculate this rate from perturbation theory. Substitute equation (50) into equation (52) and find

$$\dot{P}_n = i\hbar H'_{0,n} a_n e^{-i\omega_n t} + \text{c.c.} \tag{53}$$

Note that we may assume that our basis states λ and ϕ_n are real, because we are free to use either the real or imaginary part of any complex unperturbed solution. Therefore, the matrix $H'_{n,n'}$ is real and symmetric. Since the expectation of velocity $(-i\hbar \mathrm{d}/\mathrm{d}x)/m$ for a real wave function vanishes identically, the Bardeen method cannot describe flow of current through the electrodes − only between them.

Now calculate the one-particle current j from the general expression (Bohm, 1951)

$$j(c) = \frac{i\hbar}{2}(\psi_x^*\,\psi - \psi^*\,\psi_x)_{x=c} = \frac{i\hbar}{2}\left(\psi_x^*\,\psi\right)_{x=c} + \text{c.c.} \tag{54}$$

at the point $x = c$, where $\psi_x \equiv \partial\psi/\partial x$. We let $x = c$ be a point within the barrier and substitute equation (51) into equation (54) to find

$$j = \left[\frac{i\hbar}{2}\left(\lambda_x\varphi_n - \lambda\varphi_{n,x}\right)_{x=c} a_n(t_1)e^{-i\omega_n t}\right] + \text{c.c.} \tag{55}$$

Now compare this with equation (53), identifying $j = \sum_n \dot{P}_n$. They are equal for all initial conditions only if we identify

$$H'_{0,n} = \frac{1}{2}\left(\lambda_x\varphi_n - \lambda\varphi_{n,x}\right)_{x=c} \tag{56}$$

for all n. In this equation, c must satisfy $a \le c \le b$ in Figure 12. We conclude that equation (56) is the general formula for Bardeen's transfer Hamiltonian.

Fermi's Golden Rule for the total transition rate gives:

$$\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{2\pi}{\hbar} H'^2_{n,0}\rho(E) \tag{57}$$

where $\rho \equiv \hbar(\mathrm{d}\omega_n/\mathrm{d}n)$ is the density of states assumed to be very closely spaced (Sakurai, 1985). This equation with the matrix element (56) substituted comprises the essential tool for calculating the current through an insulating barrier.

8 CURRENTS AND TORQUES IN MAGNETIC TUNNEL JUNCTIONS

8.1 Currents

For adaptation (Slonczewski, 2005) of the Bardeen method to the MTJ illustrated schematically in Figure 13(a), a stationary basis state $|p, \sigma\rangle$ within the left ferromagnetic electrode $\mathrm{F_L}$ is assigned the orbital index p and majority/minority spin $\sigma = \pm$ quantized along axis **l**. It satisfies $(H + eV - \epsilon_{p,\sigma})|p, \sigma\rangle = 0$, and decays exponentially within the barrier, considered semi-infinite in width when defining the basis states, as in Section 7.2. From this point forward, $-V$ is the external voltage applied to $\mathrm{F_L}$. Here, $H = (\mathbf{p}^2/2m) + \Sigma_\sigma|\sigma\rangle U_\sigma(x, y, z)\langle\sigma|$, where the potential U_σ depends on spin $\sigma(= \pm)$ within the ferromagnets but not within the barrier. Within $\mathrm{F_R}$, a similar state satisfies $(H - \epsilon_{q,\sigma'})|q, \sigma'\rangle = 0$ with quantization axis **r**. Because the barrier is assumed to dominate all other resistances of this circuit, the spin channels are shown in Figure 13(b) as shorted in each magnet and external-contact region by spin-lattice relaxation due to spin-orbit coupling. One may disregard *spin accumulation* and the related distinction between electric and

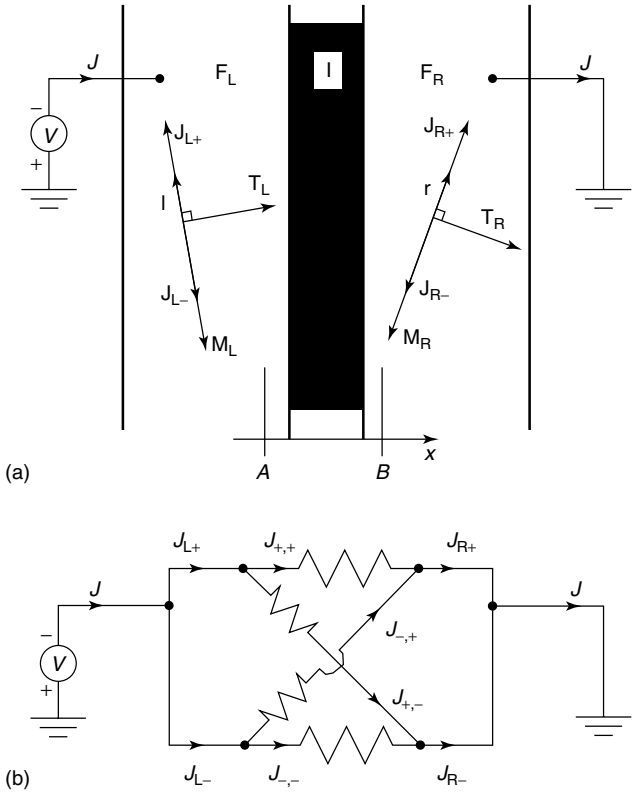

Figure 13. (a) Scheme of magnetic tunnel junction and key to notations. (b) Equivalent circuit for spin-channel currents and further key to notations.

electrochemical potentials which were important previously in connection with metallic spacers. U_σ includes all elastic terms arising from atomic disorder due to alloying, defects, interfacial atomic interdiffusion, and so on. The state indices p, q simply enumerate the exact eigenstates $|p,\sigma\rangle$, $|q,\sigma'\rangle$ of H in the Bardeen basis. Each such state incorporates effects of all multiple elastic scatterings without limit.

Employing the spinor transformation connecting quantization axes **l** and **r**, the transfer matrix element takes the form

$$\langle p,\sigma|H-\varepsilon|q,\sigma'\rangle = \begin{bmatrix} \gamma_{p,+;q,+}\cos\frac{\theta}{2} & \gamma_{p,+;q,-}\sin\frac{\theta}{2} \\ -\gamma_{p,-;q,+}\sin\frac{\theta}{2} & \gamma_{p,-;q,-}\cos\frac{\theta}{2} \end{bmatrix} \quad (\sigma,\sigma'=\pm) \tag{58}$$

Here the purely orbital factor $\gamma_{p,\sigma;q,\sigma'}$ is evaluated by extending our tunnel matrix expression (56) to three dimensions. Then, inclusion of spin indices gives the expression

$$\gamma_{p,\sigma;q,\sigma'}(x) = \frac{-\hbar^2}{2m}\int \mathrm{d}y\mathrm{d}z(\psi_{p,\sigma}\partial_x\varphi_{q,\sigma'} - \varphi_{q,\sigma'}\partial_x\psi_{p,\sigma})_{x=c} \tag{59}$$

Here the integral is over unit area with coordinate $x = c$ lying inside the barrier. The energies $\epsilon_{p,\sigma}$ and $\epsilon_{q,\sigma'}$ may differ only infinitesimally from a fixed value ε. The Hamiltonian H, the left ($\psi_{p,\sigma}$) and right ($\varphi_{q,\sigma'}$) orbital wave functions, and these matrix elements (59) are real.

Only the neglect of cross-barrier overlaps $\langle p,\sigma|q,\sigma'\rangle$ allows use of the Fermi golden rule (57) of perturbation theory which is strictly valid only for an orthonormal basis. Substitution of the perturbation (58) into this rule is followed by summation over the initial states in the energy band of width eV. Thus, for infinitesimal V, the partial electric current density flowing between channel σ in $\mathrm{F_L}$ and channel σ' in $\mathrm{F_R}$ becomes

$$J_{\sigma,\sigma'} = \frac{-2\pi e^2 V}{\hbar}\sum\nolimits'_{p,q}\langle p,\sigma|H-\varepsilon_\mathrm{F}|q,\sigma'\rangle^2 \tag{60}$$

at $T = 0$ K. The $'$ in $\sum'_{p,q}$ imposes the conditions $\varepsilon_\mathrm{F} < (\varepsilon_{p,\sigma}, \varepsilon_{q,\sigma'}) < \varepsilon_\mathrm{F} + eV$.

8.2 Genesis of polarization factors

Although MTJ relations depending on polarization factors are often used to interpret experiments, their validity is theoretically justified only under a severe restriction: The barrier is so thick that only a narrow selection of basis functions on each side penetrates it. To explain, consider the Schroedinger equation in two dimensions within the region of a flat barrier of height B:

$$\left[\frac{-\hbar^2}{2m}\left(\partial_x^2+\partial_y^2\right)+B-E_\mathrm{F}\right]\psi = 0 \tag{61}$$

A solution is

$$\psi \propto e^{-\kappa_x x}\cos(k_y y+\beta) \tag{62}$$

and the eigenvalue equation may be written

$$\kappa_x^2 = k_y^2+\kappa, \quad \kappa = \left[2m(B-E_\mathrm{F})/\hbar^2\right]^{1/2} \tag{63}$$

This equation says that the greater the y-momentum, the steeper the decay of ψ. Therefore the tunnel current concentrates near the single state with $k_y = 0$. The barrier collimates the current. Under this extreme condition, drop the indices p and q. On both sides of the barrier, the wave functions $\psi_\sigma \propto e^{-\kappa x}$ and $\varphi_{\sigma'} \propto e^{\kappa x}$ are independent of y. The matrix element (59) reduces to

$$\gamma_{\sigma,\sigma'} = \frac{-\hbar^2}{m}\kappa\int \mathrm{d}y\psi_\sigma\varphi_{\sigma'} \tag{64}$$

In the notation of Figure 13(b), the total tunnel electric current density flowing from R to L is

$$J = \Sigma_{\sigma,\sigma'}J_{\sigma,\sigma'} \tag{65}$$

with

$$J_{\sigma,\sigma'} = c_1 e^{-2\kappa w}\begin{pmatrix} \psi_+^2\varphi_+^2\cos^2(\theta/2) & \psi_+^2\varphi_-^2\sin^2(\theta/2) \\ \psi_-^2\varphi_+^2\sin^2(\theta/2) & \psi_-^2\varphi_-^2\cos^2(\theta/2) \end{pmatrix} \tag{66}$$

for any x within the barrier. Here w is the barrier thickness and the constant c_1 results from integrating $\int \mathrm{d}k_y$. For a rectangular barrier, the relative error of the Bardeen approximation is of the order $\exp(-kw)$ (Duke, 1969).

Substitute the identities

$$2\cos^2(\theta/2) = 1+\cos\theta \quad \text{and} \quad 2\sin^2(\theta/2) = 1-\cos\theta \tag{67}$$

to find

$$J = \frac{c_1}{2}e^{-2\kappa w}\left[(\psi_+^2+\psi_-^2)(\varphi_+^2+\varphi_-^2)+(\psi_+^2-\psi_-^2)\times(\varphi_+^2-\varphi_-^2)\cos\theta\right] \tag{68}$$

This may be written

$$J(\theta) = J_0(1+\iota\cos\theta), \quad \iota = P_\mathrm{L}P_\mathrm{R} \tag{69}$$

where J_0 is constant and the right and left *tunnel-polarization* factors are

$$P_{\rm L} = \frac{\psi_+^2 - \psi_-^2}{\psi_+^2 + \psi_-^2}\ , \quad P_{\rm R} = \frac{\varphi_+^2 - \varphi_-^2}{\varphi_+^2 + \varphi_-^2} \tag{70}$$

Note that the polarization factor relevant to tunneling is evaluated at any $x = c$ within the barrier. A realistic evaluation of J_0 generally requires *ab initio* numerical computation. Experimental data for the resistance $R(\theta)$ are often summarized by the magnetoresistance ratio

$$\mathrm{MR} \equiv \frac{R(\pi) - R(0)}{R(0)} = \frac{J(0) - J(\pi)}{J(\pi)} \tag{71}$$

Whenever polarization factors are legitimate, this formula reduces to that of Julliere's model (Julliere, 1975)

$$\mathrm{MR} = \frac{2P_{\rm L}P_{\rm R}}{1 - P_{\rm L}P_{\rm R}} \tag{72}$$

according to equation (69). (For more MTJ theory, see **Theory of Spin-dependent Tunneling, Volume 1** and **Spin-dependent Tunneling: Role of Evanescent and Resonant States, Volume 5**.)

8.3 Torques

Now apply the torque relations (27) and (28). (Some caution is demanded by the fact that the electron collimating effect of tunneling may cause $d_{\rm impact}$ in MTJs to be greater than that present with metallic spacers.) Substitute the relations

$$J_{{\rm L},\sigma} = J_{\sigma,+} + J_{\sigma,-}, \quad J_{{\rm R},\sigma'} = J_{+,\sigma'} + J_{-,\sigma'}, \quad (\sigma, \sigma' = \pm) \tag{73}$$

implied by the circuit diagram in Figure 13. The torque on the right magnet becomes

$$T_{\rm R} = -\left(\frac{\hbar\tau_{\rm R}J_0}{2e}\right)\sin\theta \tag{74}$$

or, in coordinate-free form

$$\mathbf{T}_{\rm R} = \left(\frac{\hbar\tau_{\rm R}J_0}{2e}\right)\mathbf{r}\times(\mathbf{l}\times\mathbf{r}) \tag{75}$$

with the torque coefficient

$$\tau_{\rm R} = P_{\rm L} \tag{76}$$

Similarly, the torque on the left magnet is

$$T_{\rm L} = -\left(\frac{\hbar\tau_{\rm L}J_0}{2e}\right)\sin\theta, \quad \tau_{\rm L} = P_{\rm R} \tag{77}$$

or, in coordinate-free form

$$\mathbf{T}_{\rm L} = \frac{\hbar\tau_{\rm L}}{2e}J_0\mathbf{l}\times(\mathbf{r}\times\mathbf{l}) \tag{78}$$

The equations (69), (76), and (78) show the very close relation between current-driven torques and magnetoconduction at the same voltage, summarized by the relation $\iota = \tau_{\rm L}\tau_{\rm R}$ connecting observables in the limit of large barrier thickness.

9 JUNCTIONS USING MGO BARRIERS

At this time (2007), rapid improvements of magnetoresistance ratio (MR) and voltage-driven torque effects in MTJs using MgO barriers are taking place. Initially, first-principle computations by Mathon and Umerski (2001) and by Butler, Zhang, Schulthess and MacLaren (2001) predicted enormous values of magnetoresistance ratio MR for epitaxial junctions of composition (001)Fe/MgO/Fe. The large MR is due to a selection rule prohibiting the transition of the minority band Δ_5 wave function at transverse momentum $k_\parallel = 0$ to the most-slowly decaying Δ_1 wave function within the MgO barrier. Subsequently (Zhang and Butler, 2004) further predicted even greater ratios in such junctions with Co or ordered FeCo substituted for Fe.

Indeed, many experiments using compositions of the class $\mathrm{Fe}_x\mathrm{Co}_y\mathrm{B}_z$/(001)MgO/$\mathrm{Fe}_x\mathrm{Co}_y\mathrm{B}_z$ reported MR as great as 270% at $T = 300$ K, but smaller than predicted (see **Magnetic Tunnel Junctions, Volume 5**). The measured MR depends greatly on extrinsic conditions including annealing, dislocations, added elements inserted at interfaces, and sputtering conditions. It appears likely that details of microstructure at interfaces mix Δ_5 and Δ_1 states, thus permitting greater minority-spin current which decreases MR from its first-principle value. Switching experiments confirm spin-transfer phenomena in MTJs (Huai *et al*., 2003; Fuchs *et al*., 2004).

Here, we predict observable signatures of voltage-driven torque whose measurement could discriminate between various effects of the microstructural conditions mentioned in the preceding text (Slonczewski and Sun, 2007). As yet no experimental tests exist. Possibly applicable methods of directly measuring the current-driven torque have appeared recently in two reports: (Tulapurkar *et al*., 2005) use an external field to orient the two magnetic moments at an angle of 30°. The torque created by an AC current flowing through the junction causes the free moment to oscillate. A voltmeter detects the DC magnetoresistive voltage proportional, by virtue of nonlinearity, to the square of the oscillation amplitude. Sankey *et al*. (2006) similarly use current-driven torque to drive ferromagnetic resonance in the free magnet. These techniques

show promise for the experimental investigation of the torque signatures predicted in the subsequent text.

Sections 7 and 8 assume the tunneling is elastic. Here we take advantage of the more general nature of relations derived there. Our present model, includes inelastic as well as elastic mechanisms of spin-polarized tunneling (Slonczewski and Sun, 2007). It is inspired in part by awareness of conductance data for $Fe_xCo_yB_z/MgO/Fe_xCo_yB_z$ of the sort shown in Figure 14. We find in the subsequent text that the antiparallel conduction G_{AP} resembling the nonanalytic function $a + b|V|$ for $|V| > 80\,\text{mV}$ (which we call *pseudolinear*), apparent in the lower curve of Figure 14, does not arise from elastic tunneling. But *inelastic* tunneling theory can explain pseudolinear voltage dependence observed for various non-MTJ tunneling junction compositions (Kirtley and Scalapino, 1990). Inclusion of inelastic tunneling is a key feature of our model for MgO-based tunneling junctions. (For MTJ experiments, see **Magnetic Tunnel Junctions, Volume 5**.)

9.1 Magnetoconductance and torkance

We employ notation compatible with the above-mentioned experimental techniques for measuring differential current- or voltage-driven torque (Tulapurkar *et al*., 2005; Sankey *et al*., 2006). In particular, we use the coefficients $G_{\sigma,\sigma'}$ of cross-channel *conductance amplitude,* defined in the subsequent text, for electric current flowing through any of the four spin channel combinations $\sigma, \sigma'(= \pm)$ (see Figure 13).

The *physical* electric conductance density flowing between spin channel σ' (R) and σ (L) of the barrier (see equation (66)) are

$$\mathrm{d}J_{\sigma,\sigma'}/\mathrm{d}V = G_{\sigma,\sigma'}(V)\langle\sigma|\sigma'\rangle^2, \quad (G_{\sigma,\sigma'}) \leq 0 \tag{79}$$

with the spin-coordinate transformation matrix elements $\langle\pm|\pm\rangle = \cos(\theta/2)$ and $\langle\pm|\mp\rangle = \pm\sin(\theta/2)$. The first-principle calculations for MTJs with (100)MgO barriers (Mathon and Umerski, 2001; Zhang and Butler, 2004), express, for $V = 0$, the conductance density for parallel and antiparallel moments with the formulas (in a different notation)

$$G_P = G_{++} + G_{--}, \quad G_{AP} = G_{+-} + G_{-+} \tag{80}$$

These equations follow easily for any V from the condition of spin conservation. When tunneling is inelastic, $G_{\sigma,\sigma'}$ necessarily varies with voltage V, as explained in the subsequent text.

Now we eschew use of polarization factors (70) because their validity in inelastic tunneling is not established. In place of equation (75), we introduce the following expression for what we may call *torkance*:

$$\frac{\mathrm{d}\mathbf{T}_R}{\mathrm{d}V} = \frac{\hbar}{4e}(G_{++} - G_{--} + G_{+-} - G_{-+})\mathbf{r} \times (\mathbf{l} \times \mathbf{r}) \tag{81}$$

Here the factor $-\hbar/2e$ converts the electric current carried by a particle flux to the equivalent current of spin angular momentum.

Equation (81) follows from equations (28) and (79). To verify equation (81) more transparently for the special case $\mathbf{l} \perp \mathbf{r}$, define the vector spin moment per unit area of one metallic nanomagnet:

$$\mathbf{S} = (\hbar/2)(n_+ - n_-)\mathbf{s} \qquad (n_+ > n_-) \tag{82}$$

where $\mathbf{s}$ is a unit vector, $n_\pm$ are total electron numbers for spin-polarized subbands $\sigma = \pm$. The spin-current density flowing rightward through the magnet is

$$\mathbf{K} = (K_+ - K_-)s \equiv (\hbar/2)(\Sigma_i v_{i,+} - \Sigma_i v_{i,-})\mathbf{s} \tag{83}$$

where $v_{i,\sigma}$ is the velocity of an occupied state. Consider the volume Ω lying between the planes marked A and B in Figure 13. The mean spin components transverse to local $\mathbf{M}$ vanish at all points outside Ω. Neglect all terms in the Hamiltonian $\mathcal{H}$ except kinetic and coulomb energies as given in equation (24). Since $\mathcal{H}$ contains no spin operators, the total vectorial spin $\mathbf{S}_{tot}$ contained in Ω changes only by inward flow of vectorial spin currents. Then its time derivative satisfies the equations

$$\dot{\mathbf{S}}_{tot} = \dot{\mathbf{S}}_L + \dot{\mathbf{S}}_R = \mathbf{K}_L - \mathbf{K}_R \tag{84}$$

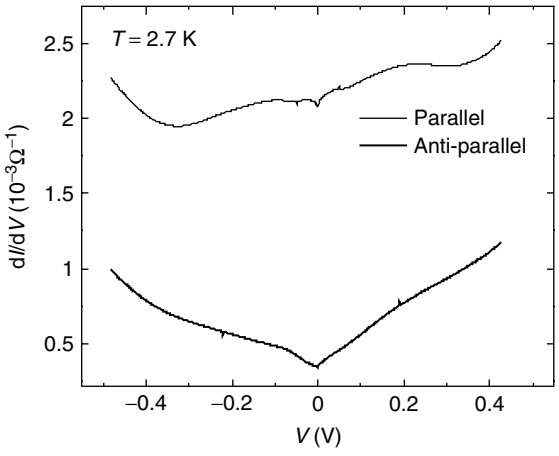

Figure 14. Measured conductance versus voltage for an MTJ having a very large MR. The parallel conductance G_P lies above, the antiparallel G_{AP} below. The composition is Co70Fe30/(8 Å)Mg-(26 Å)MgO/Co70Fe30. Junction dimensions are $240 \times 80\,\mu\text{m}^2$. (Unpublished data, by courtesy of S. S. P. Parkin.)

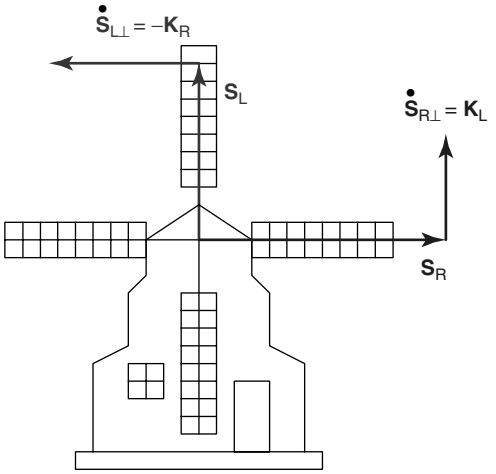

Figure 15. (Colored on line) Illustrating relations between pseudo-torque and spin-current vectors when moments are perpendicular. Assumed is the usual case in which each spin-current vector $\mathbf{K}_{\mathrm{L}}$ and $\mathbf{K}_{\mathrm{R}}$ have the same sign relative to $\mathbf{S}_{\mathrm{L}}$ and $\mathbf{S}_{\mathrm{R}}$, respectively.

The Bardeen method predicts only pseudotorque vector components lying within the $\mathbf{l}$–$\mathbf{r}$ plane. Now consider the special case $\mathbf{l} \perp \mathbf{r}$. Since $\dot{\mathbf{S}}_{\mathrm{L}} \bullet \mathbf{l} = \dot{\mathbf{S}}_{\mathrm{R}} \bullet \mathbf{r} = 0$, we have the cross-relations $\dot{\mathbf{S}}_{\mathrm{L}\perp} = -\mathbf{K}_{\mathrm{R}}$ and $\dot{\mathbf{S}}_{\mathrm{R}\perp} = \mathbf{K}_{\mathrm{L}}$. See Figure 15. According to equation (79), the $\perp$ condition implies that, from equation (83), $K_{\mathrm{L}\pm}$ has 1/2 the strength it would have for the given $G_{\sigma,\sigma'}$ if the spin axes were optimally aligned:

$$\mathrm{d}K_{\mathrm{L}\sigma}/\mathrm{d}V = \left(\frac{1}{2}\right)\left(\frac{-\hbar}{2e}\right)\left(G_{\pm,+} + G_{\pm,-}\right) \tag{85}$$

The result of combining this with the first of equations (83) and substituting into $\dot{\mathbf{S}}_{\mathrm{R}\perp} = \mathbf{K}_{\mathrm{L}}$ agrees with equation (81).

9.2 Elastic tunneling

Consider a special phenomenological model of F/MgO/F having symmetric chemical composition exemplified by the MTJ whose conductances are plotted in Figure 14. Compose each channel current density of elastic and inelastic terms: $J_{\sigma,\sigma'} = J^{\mathrm{el}}_{\sigma,\sigma'} + J^{\mathrm{inel}}_{\sigma,\sigma'}$. Define a tunnel-rate coefficient $U_{\sigma,\sigma'}$ proportional to the mean-square matrix element for elastic tunneling between the orbital states of spin channels $\sigma(=\pm)$ and $\sigma'(=\pm)$. It is averaged over the index p of real Bardeen orbital basis states $|p,\sigma\rangle$ on the left and over q of $|q,\sigma'\rangle$ on the right, with the factor depending on θ omitted. Including all other factors in the conventional tunneling expression for current except the state densities $\rho_\sigma, \rho_{\sigma'}$, it may be approximated by the form

$$U_{\sigma,\sigma'} = Ce^{-2\kappa d}\overline{\langle p,\sigma|H|q,\sigma'\rangle^2} \tag{86}$$

where κ is the decay coefficient for a real pseudo-Bloch function with $k_\parallel = 0$ and symmetry type Δ_1 having its energy within the forbidden band of MgO (Mathon and Umerski, 2001; Zhang and Butler, 2004). The predicted local density in the $\sigma = -$, Δ_5-propagation channel at $\geq$3 atomic layers of MgO from the initial F/I interface amounts to $\lessapprox 10^{-2}$ times that of the $\sigma = +$, Δ_1-channel. (See Figure 7 of Butler, Zhang, Schulthess and MacLaren, 2001.) This prediction makes reasonable our neglect of tunneling via the Δ_5 channel in experimental MTJs. We assume that disorder or dislocations within the electrodes or interface regions enables the $\sigma = -$, Δ_5-state of an electrode to couple to the Δ_1-channel of MgO to an extent governed by details of the atomic-scale structure.

For finite V, we may integrate the transition rate of the golden rule (57) with respect to V. Then, in view of the relation (60), the current density due to elastic tunneling at $T = 0\,\mathrm{K}$ reduces to the phenomenological form

$$J^{\mathrm{el}}_{\sigma,\sigma'}(V,\theta) = U_{\sigma,\sigma'}\langle\sigma,\sigma'\rangle^2\int_0^V \mathrm{d}v\rho_\sigma(v-V)\rho_{\sigma'}(v) \tag{87}$$

upon adjustment of C. Here, for convenience, we have replaced the energy ε argument in the state density ρ_σ, measured from the Fermi level $\varepsilon_{\mathrm{F}} = 0$, with voltage using $\varepsilon = eV$. We assume that, whatever lack of symmetry is present in this system, it will not be in the composition, therefore not in the state density ρ_σ. Rather it will lie in the coefficient $U_{\sigma,\sigma'}$, reflecting asymmetry of the concentration of defects or dopants in the interfacial microstructure; thus we omit the subscripts L and R from ρ_σ.

In many cases, as in Figure 14, the relative dependence of G_{P} on V is much weaker than that of G_{AP}. Thus, we take G_{P} constant and assume, to first order in v,

$$\rho_+ = \text{ const.}, \quad \rho_- = \rho_{-,0} + \rho_{-,1}v \tag{88}$$

Then in view of equation (79), equation (87) reduces in first order to

$$\begin{aligned} G^{\mathrm{el}}_{++} &= U_{++}\rho_+^2, \quad G^{\mathrm{el}}_{+-} = U_{+-}\rho_+(\rho_{-,0} + \rho_{-,1}V) \\ G^{\mathrm{el}}_{-+} &= U_{-+}\rho_+(\rho_{-,0} - \rho_{-,1}V), \quad G^{\mathrm{el}}_{--} = U_{--}\rho^2_{-,0} \end{aligned} \tag{89}$$

Notice here that U_{+-} is distinct from U_{-+} because breaking of the selection rule forbidding coupling of a $k_\parallel = 0$ minority state in a magnetic electrode to Δ_1 in MgO is allowed only by disorder in the electrode or interface, or presence of a foreign interfacial layer. Thus U_{+-} and U_{-+} depend on microstructural conditions which may differ on the two sides of the barrier. In an MTJ having large MR, such as the one in Figure 14, G^{el}_{--} is anyway small, so no correction is attempted.

Substitution of equation (89) into (80), gives the linear form $G_{\mathrm{AP}} = a + bV$ and not the *broken* linear form $a + b|V|$ which would reasonably represent the data appearing in Figure 14. To obtain a better representation of the data, we consider the possibility of inelastic tunneling in the subsequent text.

9.3 Inelastic tunneling

The following argument sketches the crux of a general theory (Kirtley and Scalapino, 1990) for the V-dependence of inelastic tunneling current density J^{inel} at $T = 0$ K: For $V > 0$, write

$$J^{\mathrm{inel}} = \int_0^V \mathrm{d}v \rho_{\mathrm{L}}(v - V) \int_0^v F^{\mathrm{inel}}(v - v')\mathrm{d}v' \rho_{\mathrm{R}}(v') \quad (90)$$

where the excitation, proportional to the spectral weight $F^{\mathrm{inel}}(v - v')$ (> 0) of excitation by some subsystem compensates for the difference $e(v - v')$ between initial and final energies in the electrodes. Then, assuming F^{inel}, ρ_{L}, ρ_{L} are constants, the result, written for both signs of V, is the broken linear function $G^{\mathrm{inel}} = \mathrm{d}J^{\mathrm{inel}}/\mathrm{d}V = F^{\mathrm{inel}}\rho_{\mathrm{L}}\rho_{\mathrm{R}}|V|$ we seek. In the present case, the nature of this subsystem (maybe magnons, electron traps at oxygen vacancies, or correlated coulomb excitation of electrons (Slonczewski and Sun, 2007)) is not known.

In the case of a perfectly ordered, epitaxial crystalline MTJ having a composition in the class (Fe,Co,FeCo)/MgO/(Fe,Co,FeCo), a quantum-theoretical selection rule forbids mixing of the minority-spin Bloch waves at $k_{\parallel} = 0$, having little-group symmetry Δ_5, with the MgO gap wave function having the lowest decay coefficient κ (Mathon and Umerski, 2001; Zhang and Butler, 2004). An enormous magnetoconductance ratio is predicted from the consequently small values of G_{+-} and G_{-+} appearing in equation (80). We assume that some inelastic mechanism provides channels additional to those of the defect-induced elastic coefficients U_{+-} and U_{-+} for breaking this selection rule. From the previous paragraph follow the formulas $G^{\mathrm{inel}}_{+-} = D_{\mathrm{R}}|V|$ and $G^{\mathrm{inel}}_{-+} = D_{\mathrm{L}}|V|$, where the adjustable coefficients satisfy $D_{\mathrm{L}} > D_{\mathrm{R}}$ or $D_{\mathrm{L}} < D_{\mathrm{R}}$ depending on which interface the inelastic mechanism favors. Since the ++ connection does not involve the selection rule, and the $--$ involves it twice, we take $G^{\mathrm{inel}}_{++} = G^{\mathrm{inel}}_{--} = 0$.

Substitution of equation (89) into (80), with $G^{\mathrm{inel}}_{\sigma\sigma'}$ included, gives

$$G_{\mathrm{AP}} = (U_{+-} + U_{-+})\rho_+\rho_{-,0} + (D_{\mathrm{L}} + D_{\mathrm{R}})|V| + (U_{+-} - U_{-+})\rho_+\rho_{-,1}V \quad (91)$$

By eliminating G_{++} between equations (80) and (81), and including $G^{\mathrm{inel}}_{\sigma\sigma'}$, one gets:

$$\mathrm{d}T_{\mathrm{R}}/\mathrm{d}V = (\hbar/4e)[G_{\mathrm{P}} + (U_{+-} - U_{-+})\rho_+\rho_{-,0} + (D_{\mathrm{L}} - D_{\mathrm{R}})|V| + (U_{+-} + U_{-+})\rho_+\rho_{-,1}V]\sin\theta \quad (92)$$

where we have neglected G_{--} altogether.

9.4 Observable signatures from magnetoconductance and torkance

With the aid of our equations (91) and (92), combined observation of G_{AP} and $\mathrm{d}T_{\mathrm{R}}/\mathrm{d}V$ may serve to reflect interfacial microstructures of a compositionally symmetric MTJ having a large magnetoconductive ratio $G_{\mathrm{P}}/G_{\mathrm{AP}}$. To illustrate this, we assume G_{P} is constant and plot schematically G_{AP} and $\mathrm{d}T_{\mathrm{R}}/\mathrm{d}V$ in Figure 16 for 5 special cases A–E reflecting terms in these equations:

1. *Symmetric reference case*, (A) with $U_{+-} - U_{-+} = \rho_{-,1} = D_{\mathrm{L}} - D_{\mathrm{R}} = 0$: Here G_{AP} has the pseudolinear dependence on $|V|$ due to inelastic scattering exemplified by the data in Figure 14. The torkance $\mathrm{d}T_{\mathrm{R}}/\mathrm{d}V = (\hbar/4e)G_{\mathrm{P}}\sin\theta$ is constant. A predicted independence of torkance on V for magnon-induced tunneling is one example of this broad phenomenological prediction (Levy and Fert, 2006).
   The remaining cases in the subsequent text illustrate possible changes from case A leaving the sums $U_{+-} + U_{-+}$ and $D_{\mathrm{L}} + D_{\mathrm{R}}$ unchanged:
2. *Asymmetry of elastic tunneling*, (B): Let $U_{+-} > U_{-+}$, which reflects the difference in degrees of disorder or dislocation density at the two F/I interfaces. G_{AP} does not change. But now the torkance makes a constant shift amounting to $(U_{+-} - U_{-+})\rho_+\rho_{-,0}\sin\theta$, according to equation (92).
3. *Dependence of state density on energy*, (C): Let $\rho_{-,1} > 0$. This does not change G_{AP} but gives the torkance a true linear dependence.

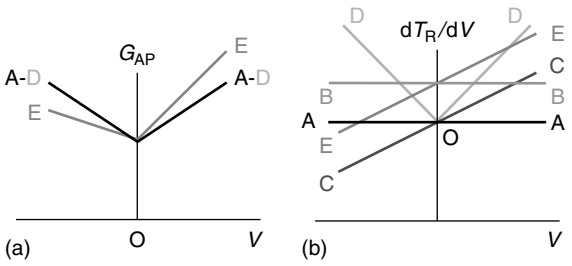

Figure 16. (Color on-line) Scheme of predicted antiparallel conductance G_{AP} (a) and torkance $\mathrm{d}T_{\mathrm{R}}/\mathrm{d}V$ (b). The separate cases A–E are described in the text.

4. *Asymmetry of distribution of inelastic tunneling centers*, (D): Let $D_L > D_R$. This causes no change in G_{AP}, but gives pseudolinear dependence to torkance. Depending on the sign of $D_L - D_R$, the torkance rises with $|V|$ as shown, or falls.
5. *Combine tunnel matrix asymmetry with dependence of ρ_- on energy*, (E): Let both $U_{+-} > U_{-+}$ *and* $\rho_{-,1} > 0$. This gives G_{AP} a true linear bias. The torkance acquires a superposition of the effects in cases B and C, namely a shift and a tilt.

It is significant how much more information about spin-dependent tunnel transport observation torkance is capable than the conductance. For example, any one of the cases A, B, C, or D could account for the data in Figure 14. They are indistinguishable in Figure 16(a), but in (b) we see significant differences in the torkance signature, potentially enabling experimental discrimination between microstructural mechanisms.

Case E is particularly interesting because the dislocation densities at the two interfaces of epitaxial (001)Fe/MgO/Fe are known to differ markedly. This difference may cause the inequality $U_{+-} \neq U_{-+}$. Indeed, a plot of G_{AP} in sample B reported by (Tiusan *et al*., 2006) reveals tilted-V behavior resembling that shown in case E of Figure 16(a). If the present model is correct, then the torkance in a pillar of the same composition should show, as a minimum, the shift and true linear tilt seen in panel (b), case E.

10 A FINAL COMMENT

Worth summarizing are the complementary natures predicted in the preceding text for currents and spin-transfer torques through metallic versus MgO-tunneling spacers: (i) When the spacer is metallic, current density J is the natural independent variable; but in the case of a barrier, the voltage V is better. (ii) At constant intermoment angle θ, the relations for $V(J)$ and torque $\mathbf{T}(J)$ predicted when the spacer is metallic are linear for a significant range of J; but the $J(V)$, $\mathbf{T}(J)$, and $\mathbf{T}(V)$ relations predicted in MTJs for general θ may be significantly nonlinear. (One linear exception is $G_P(V)$ and others are $\mathbf{T}(V)$ in the special cases A and B illustrated in Figure 16.) (iii) With a metallic spacer, the $V(\theta)$ and $\mathbf{T}(\theta)$ relations are typically not unique under any condition; but with a tunneling barrier *at given* V, they *are* simple: $J \propto \cos\theta$ and $\mathbf{T} \propto \sin\theta$.

High-temperature Superconductivity – Magnetic Mechanisms

Michael R. Norman
Argonne National Laboratory, Argonne, IL, USA

1 A BRIEF HISTORY – PART 1

The histories of superconductivity and magnetism have been much intertwined. The discovery of the Meissner effect in 1933, where magnetic flux is expelled from a superconductor as it is cooled below its transition temperature T_c, demonstrated that superconductors were more than just perfect conductors, leading to the famous proposal by London of the existence of a macroscopic condensate that accounts for the supercurrent. This was quite startling given the fermionic nature of the charge carriers in a metal, whose statistics do not prefer condensate formation as in the case of bosons. This idea was codified by Ginzburg and Landau in 1950, who introduced an order parameter field describing the condensate of electrons. The resulting Ginzburg–Landau Hamiltonian has been exploited in many areas of physics, including those dealing with the origin of the universe. One of the early successes of the Ginzburg–Landau theory was the prediction of type II superconductivity by Abrikosov in 1957, in which magnetic flux penetrates in the form of quantized vortices above a lower critical field H_{c1}. Recently, such vortices have been observed in cold atom condensates as well.

It was the development of a microscopic theory by Bardeen, Cooper, and Schrieffer (BCS) in 1957 and the subsequent proof by Gor'kov in 1959 of the equivalence of this theory to the Ginzburg–Landau formalism which began the modern era of superconductivity (Schrieffer, 1964). The crucial finding of Cooper in 1956 was that in the presence of a Fermi sea, arbitrarily weak attraction could lead to pair formation. Such pairs behave as bosons, thus explaining how a condensate could exist. The attraction that forms the pairs is a consequence of the positive ions and the fact that the ions and electrons have different timescales. Figure 1 illustrates how this works. Positive ions are attracted to negative electrons. This polarizes the ions toward the electron. When the electron leaves, a second electron sees this positive cloud and is attracted to this location, leading to pair formation. As the interaction is local in space, one forms s-wave pairs that are spin singlets by fermion antisymmetry. The pairs form despite the presence of the Coulomb repulsion of the individual electrons as they are at the same place, but at different times. Once the electrons become energetic enough relative to the ion vibrations (phonons), the attraction goes away, and the Coulomb repulsion wins out. This 'retardation' effect is responsible for limiting the superconducting transition temperature of electron–phonon systems to values significantly smaller than room temperature.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

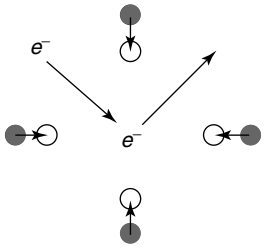

Figure 1. The electron–phonon interaction leads to an induced attraction between electrons. Arrows joining circles show displaced ions; the timescale of these ions for relaxation back to their original positions is slow compared to the electron dynamics.

The development of the BCS theory also led to the understanding of why proximity to magnetism is usually detrimental to superconductivity. In 1960, Abrikosov and Gor'kov showed, using the powerful Matsubara technique for finite temperature quantum field theory, that magnetic impurities are pair breaking (Abrikosov and Gor'kov, 1961). This result is easy to appreciate, since spin flip scattering will destroy singlet pairs. This argument was generalized to the dynamic case by Berk and Schrieffer, who showed, by summing a ladder series representing repeated scattering between the two electrons of the pair, that ferromagnetic spin fluctuations were detrimental to spin singlet superconductivity (Berk and Schrieffer, 1966) (Figure 2).

However, Fay and Layzer (1968) turned this argument around. The same formalism can be used to show that ferromagnetic spin fluctuations will promote spin triplet pairing, which is p wave due to fermion antisymmetry. This relies on the fact that the bare contact interaction is zero in the triplet channel (due to the Pauli exclusion principle), but the induced interaction (again, from the ladder sum of repeated

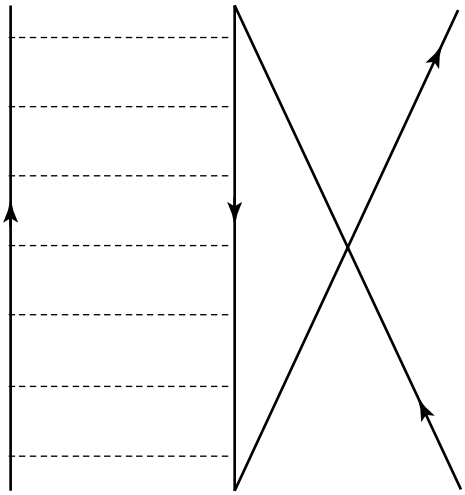

Figure 2. Particle–particle interaction from spin fluctuations. Note the particle–hole ladder sum buried inside this diagram.

scattering of two electrons via spin fluctuations shown in Figure 2) is attractive. Physically, this 'attraction' is due to the fact that an up spin electron prefers to have other up spin electrons nearby. The node in the pair wave function for the p-wave case acts to prevent the two electrons from coming too close together, thus minimizing the detrimental effects due to the direct Coulomb repulsion. They suggested that this mechanism could apply to nearly ferromagnetic metals such as Pd and also to the charge-neutral case of ^{3}He.

In 1972, Osheroff, Richardson, and Lee indeed discovered p-wave superfluidity in ^{3}He. It was soon realized that there were two superfluid phases, an anisotropic A phase and an isotropic B phase. This was difficult to understand, since the free energy of the isotropic phase should be the lowest according to Ginzburg–Landau theory. But in the following year, Anderson and Brinkman (1973) showed how the anisotropic A phase could be stabilized. The development of an energy gap removes some of those spin fluctuations that lead to pairing in a spin fluctuation model, thus leading to a decrease in the pairing kernel. This gapping effect is less pronounced in the anisotropic A phase than in the isotropic B phase, explaining how the A phase can be stabilized. This would seem to have been the 'smoking gun' for spin fluctuations, but in subsequent years, it was realized that there are many contributions to the pairing kernel besides spin fluctuations, such as density fluctuations, transverse current fluctuations, and so on. In fact, alternates to spin fluctuation theory have been proposed in the case of ^{3}He, including the 'nearly localized' approach of Vollhardt and the polarization potential model of Bedell and Pines (Vollhardt and Wolfle, 1990).

At this point, an important issue should be realized. Unlike the electron–phonon case where electrons and ions can be approximately treated as separate systems, the spin fluctuations themselves are composed of electrons. This makes the whole notion of 'pairing glue' suspect in this case. One consequence of this is that spin fluctuations do not appear to obey Migdal's theorem. How this theorem works for the classic phonon case is as follows. The ratio of the electron mass to the ion mass is very small, thus leading to a controlled perturbation expansion. For most cases, it is sufficient to stop at lowest order when evaluating the electron and phonon self-energies. The exception is the pairing instability, which requires summing a ladder series of repeated scattering. This neglect of vertex corrections, though, is not generally valid in the case of spin fluctuations, as shown by Hertz, Levin, and Beal-Monod (1976).

In 1979, Frank Steglich's group discovered superconductivity in the heavy electron alloy $CeCu_2Si_2$. This came in the face of existing wisdom that proximity to magnetism was deadly for superconductivity in metals (^{3}He obviously differs in that its pairs are composed of charge-neutral atoms). Soon,

several of these materials were discovered, and one of them, UPt_3, was known to exhibit strong spin fluctuation behavior. As expected, various spin fluctuation theories based on ^{3}He were proposed to explain the superconductivity seen in these materials. But subsequent neutron scattering revealed that these metals were nearly antiferromagnetic, rather than nearly ferromagnetic. In 1986, several theories were formulated for heavy fermions on the basis of neutron-scattering data (Miyake, Schmitt-Rink and Varma, 1986; Scalapino, Loh and Hirsch, 1986). The prediction was the formation of a singlet pair, this time due to the fact that in the presence of antiferromagnetic correlations an up spin electron prefers to be surrounded by down spin electrons. To avoid the strong on-site Coulomb repulsion, the pair state has d-wave symmetry. For a simple cubic lattice, the pairs take the form $(x^2-y^2) \pm i(3z^2-r^2)$. In real space, this pair wave function corresponds to six lobes that point from a given atomic site to its near neighbors.

In hexagonal symmetry, this two-dimensional group representation instead becomes isomorphic to $L = 2$, $M = \pm 1$ spherical harmonic. This E_{1g} model is a leading candidate to describe various experimental data in UPt_3, including the observation of the three different superconducting phases seen in the H, T phase diagram (Joynt and Taillefer, 2002). But problems with this model have led to a variety of other proposals, including the A, B model of Garg (two nearly degenerate single dimensional group representations), the p-wave model of Machida, and the f-wave model of Norman and Sauls. This last model (E_{2u}) provides a particularly good description of the H, T phase diagram, thermal conductivity, and transverse ultrasound data (Sauls, 1994). Triplet models (p, f) for UPt_3 are particularly attractive, since there has been no observed change in the Knight shift (i.e., the static spin susceptibility) when going below T_c, as opposed to other heavy fermion superconductors such as UPd_2Al_3 and $CeCu_2Si_2$ (Tou, Ishida and Kitaoka, 2005). The point to be made, though, is that despite many claims in the literature, the actual pairing symmetry of any heavy electron superconductor is unknown at present.

2 A BRIEF HISTORY – PART 2

In early 1986, high-temperature superconductivity was discovered by Bednorz and Mueller in the doped perovskite $La_{2-x}Ba_xCuO_4$ (LBCO) (Bednorz and Müller, 1986). It was not until November of that year, though, before the results were verified and thus led to wide-scale recognition. By January of 1987, superconductivity above the temperature at which air liquefies was found in the related compound $YBa_2Cu_3O_7$ (YBCO) by Chu and collaborators. The same month, a theory for these materials was proposed by Anderson (1987). He recognized that the undoped compound La_2CuO_4 would likely be a Mott insulator. He speculated that the Néel (antiferromagnetic) order of the insulator would be melted by quantum fluctuations (due to the low spin $S = 1/2$ of the d^9 Cu ion and the two-dimensional nature of the CuO_2 planes). Although Néel order was discovered subsequently, it indeed disappears when only a few percent of holes are doped into the material. Anderson denoted this melted Néel state as a *resonating valence bond* (*RVB*) state, which represents a liquid of spin singlet pairs. When the system is doped, the presence of charge carriers causes this spin pairing state to condense into a superconducting state. Originally, it was thought that the resulting pair symmetry would be s-wave-like, but subsequent work in 1988 predicted d-wave symmetry instead (Kotliar and Liu, 1988; Zhang, Gros, Rice and Shiba, 1988).

It was not long after Anderson's theory was announced in 1987 that more traditional spin fluctuation–based approaches were brought to bear on this matter. Bickers, Scalapino, and Scalettar observed that the 3D pairing state discussed earlier in the context of heavy fermion materials would reduce to $dx^2 - y^2$ in two dimensions (Bickers, Scalapino and Scalettar, 1987). Scalapino (1995) subsequently gave an intuitive picture of how such a pair state arises. In momentum space, the zero frequency limit of the real part of the effective potential coming from the Coulomb interaction is repulsive for all wave vectors, with a maximum at a wave vector (π, π) which would be the ordering wave vector for the undoped antiferromagnet (Figure 3). But Fourier transformed into real space, the effective potential has Friedel oscillations. Although obviously repulsive at short distances, the potential is attractive for near neighbor separations (Figure 3). In momentum space, this is reflected in the gap equation, where the sign change of the d-wave tight binding gap function $\Delta(\mathbf{k}) = \cos(k_x a) - \cos(k_y a)$ upon translation by (π, π) compensates for the repulsive sign of the potential V: $\Delta(\mathbf{k}) = \Sigma_{\mathbf{k}'} V_{\mathbf{k}\mathbf{k}'} \Delta(\mathbf{k}')$ where the pairing kernel $V_{\mathbf{k}\mathbf{k}'} = U + J(\cos(q_x a) + \cos(q_y a))$ with $\mathbf{q} = \mathbf{k} - \mathbf{k}'$, U positive and J negative.

Despite this initial success, there were no indications from experiment at that time supporting the existence of a d-wave pairing state. In fact, because the cuprates are somewhat dirty systems replete with impurities, the feeling was that the order parameter would have to be s-wave-like to avoid pair breaking. To understand this, we note that the d-wave order parameter changes sign under a reflection operation $xy \rightarrow yx$. Any impurity scattering that mixes these two states destroys the d-wave phasing relation.

In the early 1990s, though, experimental evidence began to emerge supporting a d-wave picture. The temperature dependence of the nuclear magnetic resonance (NMR) spin relaxation rate, the Knight shift, and the in-plane penetration depth

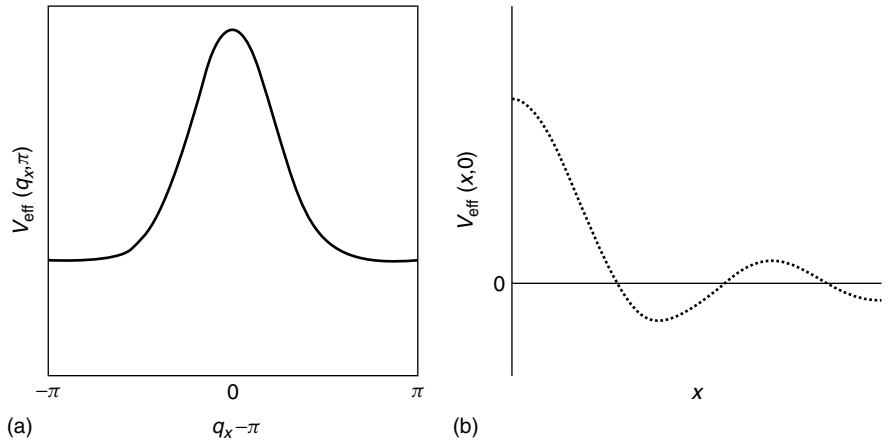

Figure 3. Effective interaction for spin fluctuation–mediated pairing (antiferromagnetic case). (a) Momentum space (a repulsive potential peaked at $\mathbf{q} = (\pi, \pi)$) and (b) real space (repulsive potential on site, attractive potential for a near neighbor separation).

did not follow the exponential behavior predicted for s-wave pairing, but rather the power law behavior predicted for a d-wave state due to the presence of a node (zero) in the order parameter. This node was subsequently imaged directly by angle-resolved photoemission. Then phase-sensitive Josephson tunneling saw the predicted sign change of the d-wave order parameter upon 90° rotation. Since then, a large body of experimental evidence has accumulated, including the dependence of T_c on impurities, that overwhelmingly confirms the d-wave nature of the pairs. At the same time, there has been great progress in the theory of spin fluctuations as applied to cuprates, as well as in solving the underlying microscopic theories based on the Hubbard model. In addition, there have been recent advances made in the RVB theories as well.

3 ELECTRONIC STRUCTURE OF THE CUPRATES

In the undoped cuprates, the copper ions are in a d^9 configuration. This corresponds to a single hole in the x^2-y^2 orbital (not to be confused with the d-wave pair state discussed earlier). Of all transition-metal oxides, the cuprates are unusual in that the copper d orbital and the oxygen p orbital have energies that are nearly degenerate (Pickett, 1989). As a consequence, the dominant energy scale in the problem is the large ($\sim$6 eV) bonding–antibonding splitting between the copper $dx^2 - y^2$ orbital and the oxygen p_x and p_y orbitals (Figure 4). This leaves the highest energy band (the antibonding one) as half filled. Adding Coulomb repulsion, this band splits into two, a lower Hubbard band and an upper Hubbard band. The resulting Mott insulating gap is of the order of 2 eV. Keeping all three bands, this is known as the *three-band Hubbard model*, but keeping

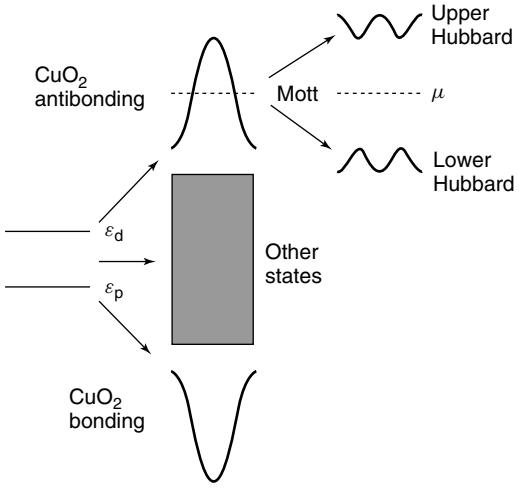

Figure 4. Electronic structure of the layered cuprates. The copper d and oxygen p levels hybridize, resulting in a partially filled antibonding band. A Mott gap due to Coulomb correlations splits this band, leading to the formation of an upper Hubbard band and a lower Hubbard band, with the chemical potential, μ, inside this gap for zero doping.

just the antibonding band it is known as the *single-band Hubbard model*. Almost all treatments assume the latter, though Varma has argued that important physics is thrown out upon such a reduction (as will be discussed later). In the limit of large Coulomb repulsion, U, one can then project onto the subspace which does not allow double occupation of the Cu site, leading to the $t - J$ model, where J, the superexchange interaction, is proportional to t^2/U and t is the effective hopping integral between Cu sites. J prefers antiferromagnetic orientation of the copper spins (one spin per site in the undoped case). This can be seen by the fact that the Pauli exclusion principle does not allow virtual double occupation unless the two spins are antialigned.

There are no exact solutions of either the single band Hubbard model or the simpler $t-J$ model in two dimensions. Approximate treatments have been done using quantum Monte Carlo, density matrix renormalization group, dynamical mean-field theory (and its various cluster extensions), and exact diagonalization of small clusters. Although there is no solid proof at this time, results are encouraging enough that there is a strong probability that a true d-wave pairing instability exists in these models. It is beyond the scope of this article to review these techniques. Instead, we give an overview of the spin fluctuation approach and its RVB counterpart, discuss these theories in relation to experimental data, and then end with a discussion of alternate mechanisms for cuprate superconductivity.

4 SPIN FLUCTUATION THEORIES

The literature on this subject is vast, so this brief review can only give the highlights. The basic idea is that in spin fluctuation theories, the pair potential V is found to be proportional to $I^2\mathrm{Im}\chi(\mathbf{q},\omega)$ where I is the effective spin interaction between electrons and $\mathrm{Im}\chi(\mathbf{q},\omega)$ is the imaginary part of the dynamic spin susceptibility, with the proportionality prefactor of order unity ($-3/2$ for spin singlet pairs and $+1/2$ for spin triplet pairs). 'I' itself is dependent on the underlying theory. For instance, in the Hubbard model, this would be the Hubbard interaction U, but if one used an effective low-energy theory, then it would be J, the superexchange interaction. At this level, the theory is equivalent to random phase approximation (RPA) where $\chi(\mathbf{q},\omega)=\chi_0(\mathbf{q},\omega)/(1-I\chi_0(\mathbf{q},\omega))$ with $\chi_0(\mathbf{q},\omega)$ the polarization bubble calculated using bare Greens functions.

There are several ways to consider going beyond RPA. One is simply to add fluctuation corrections to $\chi(\mathbf{q},\omega)$. To understand this approach (Lonzarich and Taillefer, 1985), we note that in a Ginzburg–Landau expansion for magnetism, the free energy would be of the form aM^2+bM^4 where M is the magnetization (staggered magnetization in the antiferromagnetic case). With fluctuations included, we note that upon factorization of M^4 one obtains a term of the form $6\langle M^2\rangle M^2$ where $\langle M^2\rangle$ is the expectation value of M^2 averaged over all statistical ensembles. This $6bM^2\langle M^2\rangle$ term then renormalizes the aM^2 term, leading to an $a_{\mathrm{eff}}=a+6b\langle M^2\rangle$, noting that a is simply the inverse (RPA) susceptibility (in statistical field theory, this is often denoted as the *Hartree approximation*). This approach has been enormously successful in describing transition-metal magnets, for instance, predicting the lack of magnetic long-range order in lower dimensions, and understanding why most magnets have transition temperatures strongly suppressed relative to mean-field (Stoner) theory. In turn, these fluctuations enter into the pair kernel, and this approach has been extensively studied by Moriya and coworkers in the context of a spin fluctuation–mediated picture for cuprate superconductivity (Moriya and Ueda, 2000, 2003).

Another way to go beyond RPA is to use dressed Greens functions rather than bare ones when constructing the polarization bubble. This is the basis behind the fluctuation exchange (FLEX) approximation (Bickers, Scalapino and White, 1989), where the self-energy used to dress the single-particle Greens functions is chosen to satisfy a certain self-consistency relation involving the free energy, the self-energy, and the Greens function (the conserving approximation of Gordon Baym). Subsequently, this method has been applied by many authors, to address not only the single-particle spectral function and the dynamic spin susceptibility but also the pairing interaction.

One issue with such approximations is that it is usually dangerous to dress the Greens functions without including vertex corrections in the spin susceptibility. In the 'two-particle self-consistent' approach of Vilk and Tremblay (1997), a similar procedure to FLEX is done, but now the interaction U (they assumed a Hubbard model) is replaced by U_{sp}, with U_{sp} a screened interaction (again chosen to satisfy certain self-consistent relations), which enters the susceptibility, $\chi(\mathbf{q},\omega)=\chi_0(\mathbf{q},\omega)/(1-U_{\mathrm{sp}}\chi_0(\mathbf{q},\omega))$, where as in FLEX χ_0 is calculated using dressed Greens functions. In essence, U_{sp} represents a constant vertex correction. More sophisticated approximations would allow U_{sp} to depend on momentum and frequency. Note that in such approaches, the U^2 prefactor of the pairing kernel is now replaced by UU_{sp}. A recent review of this and related approaches based on dynamical mean-field theory (and its cluster extensions) has been offered by Tremblay, Kyung, and Senechal (2006).

One can, of course, attempt to go beyond these approximations by performing a systematic diagrammatic expansion including vertex corrections, for instance, the work of Doug Scalapino and coworkers (Bulut, 2002). These authors have used quantum Monte Carlo simulations as a fundamental check of their work (as has the Tremblay group). The limitation is that such quantum Monte Carlo simulations cannot be carried out at low temperatures because of the so-called fermion sign problem (the many-body wave function having both positive and negative regions in the fermionic case leads to the problem of negative probabilities in the context of the simulations).

And, there have been some attempts to combine all of these ideas into a single approach. A good example is the extensive work of Chubukov and collaborators on a quantum field theoretical approach to the spin fluctuation problem, dealing with matters concerning the strong influence of quantum and thermal fluctuations, with the resulting non-Fermi liquid behavior. Space prohibits an adequate summary of this work,

and the reader is referred to a review article done by this group (Abanov, Chubukov and Schamlian, 2003).

Finally, one can go via the phenomenological route and replace $\chi(\mathbf{q}, \omega)$ in the pairing kernel by the experimental dynamic spin susceptibility. This approach has been exploited by a number of authors, in particular David Pines and coworkers (Monthoux and Pines, 1994), where they modeled $\chi(\mathbf{q}, \omega)$ based on the NMR data of Slichter's group. Subsequent work has exploited the growing amount of data for $\chi(\mathbf{q}, \omega)$ obtained by inelastic neutron scattering (INS).

So, what is the upshot of these approaches? For doping ranges relevant for experiment, they predict d$x^2 - y^2$ pairing. The physics is essentially equivalent to that discussed earlier in this article, and in the context of the cuprates, this was first discussed by Bickers, Scalapino and Scalettar (1987) as mentioned before. But what does this all mean when addressing experimental data?

5 SPIN FLUCTUATION THEORIES – CONFRONTING EXPERIMENT

First, we deal with the 'if' story; that is, does d-wave pairing really emerge from the underlying Hamiltonians (single-band Hubbard, $t - J$) that underlie these spin fluctuation approaches? Interestingly, the jury is still out on this question. The most detailed diagrammatic studies of Scalapino and coworkers (Bulut, 2002) have not definitely answered this question (the issue being whether vertex corrections do or do not suppress the pairing instability). Quantum Monte Carlo simulations have yielded conflicting results, some indicating an enhancement of pairing, others not, though the most recent studies indicate an enhancement (Sorella *et al*., 2002). The issue, of course, is the inability to access very low temperatures because of the fermion sign problem.

Of course, virtually all such approaches do yield d-wave pairing (within a given approximation), but the predicted values of T_c vary quite a bit. This even occurs in phenomenological models, where there was an interesting debate between two groups (Pines and Levin) concerning whether such models did or did not generate high T_c. Besides the obvious differences of the two phenomenologies (choice of U_{eff}, etc.), the main issue concerned how far in energy the dynamic susceptibility extended (Schuttler and Norman, 1996). Most INS studies are confined to less than 100 meV, but we now know that significant weight must be present beyond this energy scale to obtain a high T_c. Fortunately, recent INS measurements on underdoped LBCO and YBCO indicate spectral weight up to and beyond 200 meV (for the undoped material, spin fluctuations extend up to 400 meV). On the other hand, the susceptibility decreases with doping, and it is certainly not clear whether there is enough magnetic spectral weight in overdoped materials to be consistent with the relatively high T_c seen.

Of course, arguing about values of T_c might seem analogous to asking how many angels can dance on the head of a pin. After all, in BCS theory, T_c depends exponentially on its coupling constant. Of more relevance is what such theories tell us about experimental data.

Let us start with the one most debated, which is the nature of the phase diagram in cuprates. There are (of course) a number of versions of this, but Figure 5 gives a representative one. Besides the well-known magnetic (Néel) insulator at low doping and the superconducting phase at intermediate doping, several other phases have been proposed. Likely, at low temperatures, the Néel state continues as a disordered (spin glass) state, though the range of doping and the ubiquity of this phase are still debated. At high dopings, there is increasing evidence that the normal state is a Fermi liquid, with scattering rates roughly quadratic in temperature and energy, and thus with well-defined single-particle (quasiparticle) states. Near optimal doping above T_c, one sees a 'strange metal' phase characterized by 'marginal Fermi liquid'–like behavior (Varma *et al*., 1989). By this, we mean a scattering rate that is linear in temperature and energy. But of most interest is the pseudogap phase in the underdoped regime, first inferred from NMR measurements, and later studied extensively by INS, infrared conductivity, tunneling, specific heat, and perhaps most spectacularly by angle-resolved photoemission (ARPES). These studies

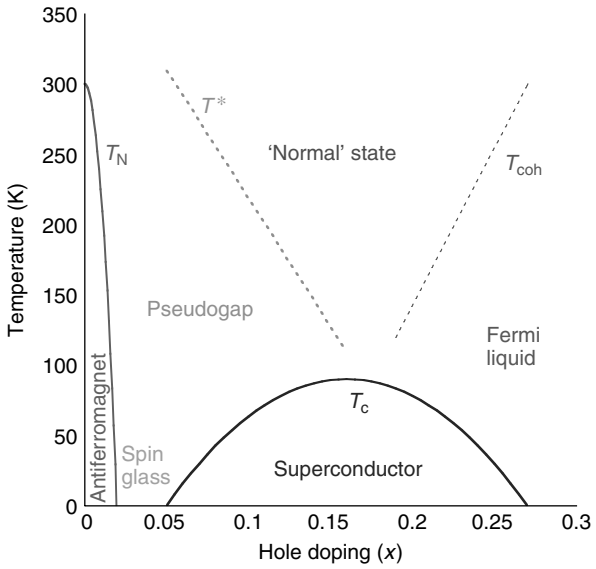

Figure 5. Phase diagram of the cuprates versus x, the number of doped holes per copper ion. Solid lines represent true thermodynamic phase transitions; dotted lines indicate crossover behavior.

indicate that an anisotropic gap emerges in the electronic excitations well above T_c. The question is about the nature of this gap.

One thought is that the pseudogap is a precursor to the superconducting gap (Randeria, Trivedi, Moreo and Scalettar, 1992). After all, in almost all magnets, the exchange splitting exists far above the ordering temperature, this temperature being strongly reduced by fluctuations as discussed in the preceding text. Stated equivalently, the exchange gap is not proportional to $\langle M \rangle^2$ but rather to $\langle M^2 \rangle$. Superconductors, though, usually do not demonstrate these effects. But cuprates are characterized by small carrier densities, short coherence lengths, and reduced (quasi-2D) dimensionality. All of these conspire to make fluctuation effects more profound. Some spin fluctuation models do advocate that the pseudogap is a pairing gap. But most assume that it is actually the magnetic exchange gap itself.

To understand this, note that because of the Mermin–Wagner theorem, long-range magnetic order at finite T would not occur in two dimensions. This is why the transition temperature of the undoped material is strongly suppressed relative to the value of J (which is of the order of 1500 K); that is, T_N is determined by residual three-dimensional coupling between the CuO_2 planes. But this 'three-dimensional' T_N is rapidly destroyed by doping. What is left then is a pseudogap state characterized by short-range antiferromagnetic fluctuations. As these are known to disappear with overdoping, this provides a natural explanation of the strong doping dependence of the T^* (pseudogap) crossover line. In some sense, the pseudogap phase is the 'renormalized classical' regime that exists above what is presumably a $T = 0$ magnetic phase transition. The effect is pronounced because of the quasi-two dimensionality (Vilk and Tremblay have demonstrated that this pseudogap is a property of two dimensions and would be very weak in the three-dimensional case (Vilk and Tremblay, 1997)).

These approaches have emphasized the potential 'quantum critical' nature of the phase diagram shown in Figure 5 (Laughlin, Lonzarich, Monthoux and Pines, 2001). The idea is that at a critical doping, antiferromagnetic fluctuations would disappear (T^* would go to zero). This purported 'quantum critical point' is buried under the superconducting dome. Is this coincidental? The spin fluctuation proponents say it is not, and note the similarity of the cuprate phase diagram to that determined in a number of heavy fermion magnets. In those cases, the systems are three dimensional, and thus the T^* line actually corresponds to the phase line for long-range ordering. And in several cases, a superconducting dome appears in the vicinity of where this phase line goes to zero temperature. This was first elucidated by Gil Lonzarich's group for $CeIn_3$ and $CePd_2Si_2$ under pressure (Mathur *et al.*, 1998), but this has now been seen for several other materials as well, including the first known heavy fermion superconductor, $CeCu_2Si_2$. This quantum critical point scenario, though, is not unique to magnetic models.

Despite first appearances, this 'nearly antiferromagnetic' picture of the pseudogap phase is quite different from the RVB one presented in the next section. In the RVB approach, the fluctuations are singlet in character, but in the spin fluctuation approach, they are antiferromagnetic in nature. Note that a singlet is $S = 0$, but an antiferromagnet corresponds to a mixture of $S = 0$ and $S = 1$, $S_z = 0$. They are obviously not the same object. This controversy is best highlighted by two recent papers, one by Barzykin and Pines (Barzykin and Pines, 2006) and the other, the RVB review article by Lee, Nagaosa, and Wen (2006). In both cases, spin susceptibility data are compared to results of the 2D Heisenberg antiferromagnet. In the former case, there is a match (Figure 6) and in the latter case there is a large discrepancy. Part of this disagreement is due to the assumed 'offset' of the susceptibility: the former assumes a temperature-independent but doping-dependent Fermi liquid component and the latter, that the only offset is due to the van Vleck contribution. But the major disagreement concerns the magnitude of J: the latter use the value of 130 meV appropriate for the insulator, but the former assume that T^* is actually J itself, and, thus, strongly doping dependent. To justify this, these authors ironically quote the RVB result that the effective exchange J_{eff} should be $J - tx$ (where t is the hopping and x is the doping).

The nature of the dynamic spin susceptibility itself is more controversial. In Figure 7, the famous 'hourglass' plot of the energy–momentum relation of the spin fluctuations is presented (Tranquada *et al.*, 2004). This was first elucidated for underdoped YBCO in its superconducting state (Arai

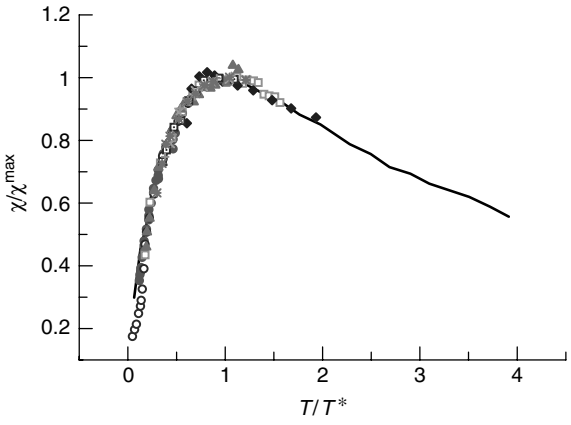

Figure 6. Comparison of the 2D Heisenberg model to experimental susceptibility data in YBCO. (Reproduced from V. Barzykin *et al.*, 2006, with permission from the American Physical Society. © 2006.) The data are scaled assuming that the effective exchange at a given doping is equal to the pseudogap onset temperature T^*.

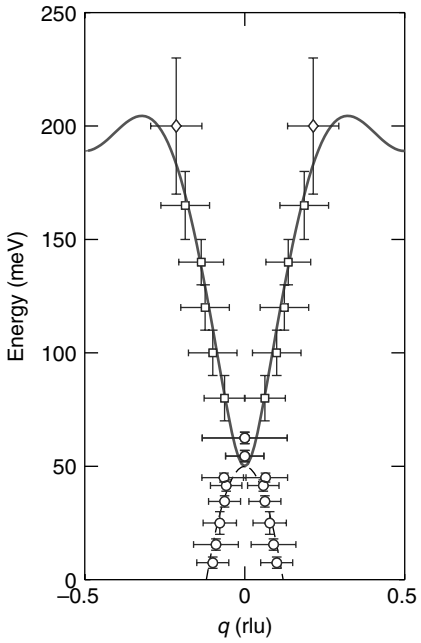

Figure 7. Hourglass-like dispersion of the spin excitations in the stripe-ordered phase of LBCO, measured with respect to $\mathbf{q} = (\pi, \pi)$, as revealed by inelastic neutron scattering. (Reproduced from J.M. Tranquada *et al*., 2004, with permission from Nature Publishing Group. © 2004.) A similar dispersion is seen in the superconducting state of underdoped YBCO (Hayden *et al*., 2004).

et al., 1999). It is characterized by strong intensity at the neck of the hourglass which occurs at a commensurate wave vector of $\mathbf{q} = (\pi, \pi)$ known as the *resonance*, with two incommensurate 'bowls' above and below. Although not apparent in Figure 7, it is now known that the hourglass has a 45° twist in momentum space, with the incommensurability below resonance oriented along the CuO bond directions and that above resonance oriented along the diagonals (Hayden *et al*., 2004).

This unusual pattern has been reproduced by various RPA-type calculations. To understand this result, note that in the superconducting state, the polarization bubble becomes $G_{\mathrm{k}}G_{\mathrm{k+q}} + F_{\mathrm{k}}F_{\mathrm{k+q}}$ where G_{k} is the normal Greens function and F_{k} the anomalous (Gor'kov) Greens function. The latter is proportional to the gap, Δ_{k}. For s-wave superconductors, the presence of a gap causes a 2Δ gap in $\mathrm{Im}\chi_0$. But because the gap is constant in the s-wave case, these two terms (*GG* and *FF*) destructively interfere in such a way that no pole develops in the RPA expression $\chi = \chi_0/(1 - I\chi_0)$. On the other hand, for the d-wave case, the two terms reinforce near $\mathbf{q} = (\pi, \pi)$ since the gap product $\Delta_{\mathrm{k}}\Delta_{\mathrm{k+q}}$ is negative (Fong *et al*., 1995). As a consequence $\mathrm{Im}\chi_0$ has a step jump at the 2Δ threshold. By Kramers–Kronig, this translates into a log divergence in the real part at $\omega = 2\Delta$, and thus a pole in χ is guaranteed at some $\omega < 2\Delta$. The dispersion of $\mathrm{Im}\chi$ away from (π, π) can either be upward (magnonlike) or downward (reverse magnonlike), depending on the Fermi surface geometry. In the latter case, one reproduces the downward part of the hourglass in Figure 7. The upper part of the hourglass is a consequence of the fact that the RPA response is typically incommensurate for frequencies above that of the (π, π) resonance, and some calculations also reproduce the 45° twist effect mentioned above (Eremin *et al*., 2005).

There is, though, an alternate explanation for the data based on 'stripes' (Tranquada *et al*., 2004). The idea is illustrated in Figure 8 (Tranquada *et al*., 1995). All of the above theories assume homogeneous behavior. But what if instead the system prefers to be inhomogeneous. To understand this, note that each doped hole in a CuO_2 plane breaks the four magnetic bonds that connect a given copper ion to its four neighbors. This is energetically costly, and one way to minimize this effect is having the holes clump together. But the long-range part of the Coulomb interaction will not prefer this clumping of charge. As a compromise, it was proposed some years ago that the system would instead organize into a lamellar phase where 'stripes' composed of the doped holes would be separated by undoped (antiferromagnetic) regions (Zaanen and Gunnarsson, 1989). This idea naturally explains why the separation of the incommensurate wave vector from (π, π) (width of the bottom of the 'hourglass' in Figure 7) scales with the doping (the well-known Yamada plot (Fujita *et al*., 2002) shown in Figure 9). In this picture, the incommensurability is due to the 'skip' of the antiferromagnetic structure across the stripe (that is, the antiferromagnetic

domains themselves are commensurate), as opposed to RPA, where the incommensurability is due to the 2D Fermi surface geometry (which under certain assumptions (Si, Zha, Levin and Lu, 1993) can also reproduce the Yamada plot). And, detailed simulations by several groups have also reproduced the hourglass itself (Uhrig, Schmidt and Gruninger, 2004). The upper part of the hourglass is just the gapped magnonlike dispersion one would obtain for an undoped two-leg ladder (which is used to model the antiferromagnetic domains). The lower part of the hourglass is due to spin-wave-like excitations associated with the stripe periodicity (in the simulations, they are due to the much weaker exchange that couples one spin ladder across a stripe to the next spin ladder). The 'twist' of the hourglass also naturally emerges from these simulations.

The important point to emphasize is how different these two explanations of the 'hourglass' are. In the RPA case, the assumption is a homogeneous 2D material. The spin excitations are derived from underlying fermionic and pair excitations (from G_k and F_k). The d-wave symmetry of the gap and the shape of the 2D Fermi surface are crucial for the obtained results. In the stripes case, though, the simulations are essentially undoped spin ladders connected by weak exchange. There are no underlying fermionic degrees of freedom. The physics is crucially dependent on the inhomogeneity of the stripes and their quasi-1D character (the spin gap associated with the upper part of the hourglass is the ladder analog of the Haldane gap associated with a linear chain of spins). In support of the 'stripes' picture, Tranquada's group has seen the hourglass as well for LBCO at $x = 1/8$ (Tranquada *et al*., 2004) which is not superconducting because of the formation of static stripes (Tranquada *et al*., 1995). On the other hand, it is quite possible that the RPA-like theories would work in this case as well if the pseudogap had d-wave symmetry. A recent ARPES study has indicated that the $T = 0$ pseudogap state indeed has the same nodal structure as the d-wave superconducting state (Kanigel *et al*., 2006), and new ARPES results indicate a similar story as well for LBCO at $x = 1/8$ (Valla *et al*., 2006).

The next experimental controversy concerns unusual features seen in the single-particle spectral function measured by ARPES and the resulting density of states measured by tunneling spectroscopy. Both find a very unusual spectral lineshape in the superconducting state (Figure 10), with a sharp peak at the gap energy followed at higher energies by a spectral dip and at even higher energies by a broad hump (peak-dip hump). It was speculated early on that this might be some strong coupling feature as seen previously in tunneling spectra for conventional superconductors. The idea is that the spectral dip represents a singularity in the electron self-energy. This results in a two-branch spectrum, the low-energy branch (associated with the sharp peak) represents a renormalized quasiparticle-like dispersion, and a higher-energy branch (the 'hump'), a dispersion which at high energies traces out the bare one (Norman *et al*., 1997). The theory for this had been worked out in by Engelsberg and Schrieffer (1963) in the context of the electron–phonon interaction. The singular energy would then be the sum of the gap energy Δ and the boson energy Ω (in their case, a phonon), and thus a subtraction of the gap and dip energies would yield Ω (the physics of this can be seen from the Feynman diagram in Figure 11). Norman *et al*. noticed that for a slightly overdoped Bi2212 sample the peak-dip-hump structure was only visible below T_c; above T_c one simply saw a single broad peak (Figure 10). On this basis, they felt that the effect was unlikely to be due to a phonon (which would of course still be present above T_c) and more likely

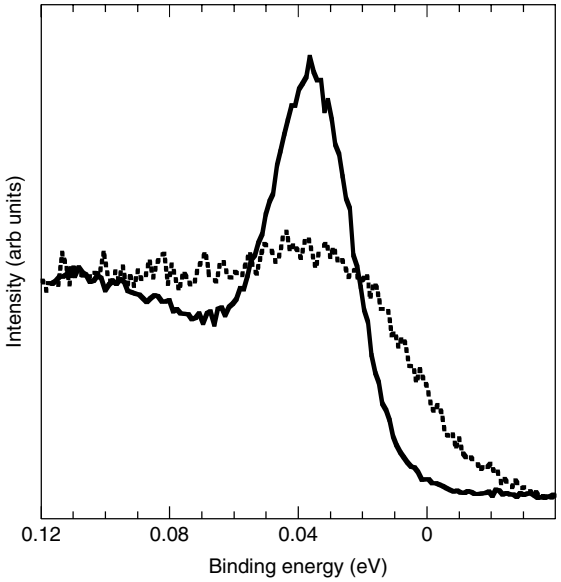

Figure 10. ARPES spectra at $k = (\pi, 0)$ for an overdoped ($T_c = 87$ K) Bi2212 sample in the normal state (dotted line) and superconducting state (solid line). (Reproduced from M.R Norman *et al*., 1997, with permission from the American Physical Society. © 1997.)

due to some kind of electronic collective excitation. Noting that (i) the peak-dip-hump effect was strongest at the $(\pi, 0)$ point of the Brillouin zone that are connected to one another by (π, π) wave vectors and (ii) the energy of the boson was inferred to be 40 meV, the same as seen for the (π, π) spin resonance in optimal doped YBCO (the neck of the hourglass in Figure 7), Norman *et al*. speculated that the boson instead was the spin resonance and in a later paper by this group, they gave evidence that the doping dependence of the boson energy was consistent with INS, which finds that the resonance energy falls with underdoping (Campuzano *et al*., 1999). This was very unusual since the gap energy increases strongly as the doping is reduced. Subsequently, Zasadzinski *et al*. (2001) traced the mode energy in great detail with tunneling, exploiting its higher-energy resolution (Figure 12). They found that the boson energy scales as $5T_c$, just as the resonance does in neutron data. Moreover, with overdoping, the boson energy approaches

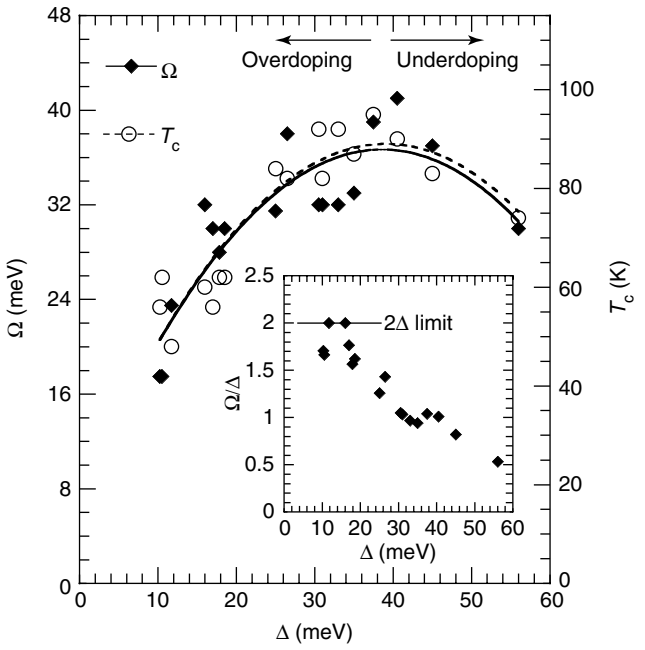

Figure 12. Resonance energy versus doping inferred from tunneling data, showing scaling with T_c. The inset demonstrates that this energy saturates to 2Δ in the overdoped limit. (Reproduced from J.F. Zasadzinski *et al*., 2001, with permission from the American Physical Society. © 2001.)

but never exceeds 2Δ, as would be expected for a collective mode inside of a 2Δ gap (as occurs in the RPA calculations discussed above).

With the development of improved (Scienta) detector technology, the momentum and frequency dependence of this effect in ARPES has been mapped out in much greater detail. The peak-dip-hump spectra in constant momentum slices energy distribution curves (EDCs) are reflected in a two-branch dispersion which is translated to a single 'S'-shaped dispersion when traced used constant energy slices momentum distribution curves (MDCs). As with the peak-dip hump, this 'S'-shaped anomaly disappears when going above T_c (Sato *et al*., 2003). All of these effects become less pronounced as one moves in the zone from the $(\pi, 0)$ point toward the d-wave node (Kaminski *et al*., 2001). Along the nodal direction, the MDC dispersion forms a kink behavior (Bogdanov *et al*., 2000) instead of an 'S', and the resulting EDC at the node itself has a 'break' (Kaminski *et al*., 2000) rather than a clear spectral 'dip'. But the spectral behavior seems to continuously evolve as a function of momentum, indicating that all the strong coupling effects have a similar origin (Kaminski *et al*., 2001).

This picture, though, has been challenged by a number of groups. Kee, Kivelson, and Aeppli (2002) have questioned whether there is enough spectral weight in the resonance (typically a few percent of the total spin fluctuation spectral

weight) to account for the strong effects seen in ARPES and tunneling. This reduces to an argument concerning the size of the interaction I in the boson spectral function $3/2I^2\chi(\mathbf{q}, \omega)$ (Abanov *et al*., 2002). More seriously, Lanzara *et al*. (2001) have seen the nodal kink in a variety of different cuprates for different dopings at essentially the same energy. They also see a weaker kinklike effect above T_c. Because of this, they speculated that the boson was instead a phonon. Extra evidence for phonons was given in later experiments that found an oxygen isotope effect (Gweon *et al*., 2004) (yet to be reproduced by other groups), and the idea was extended by Cuk *et al*. (2004) to deal with other regions of the zone (they propose a breathing mode to explain the nodal 'kink' and a buckling mode to explain the antinodal 'S'). Cuk *et al*. advocate that the rapid appearance of the 'S' below T_c is due to the gapping of the internal fermion line in the Feynman diagram in Figure 11. Further support for this picture has been given in a recent scanning tunneling microscopy (STM) study, where an analysis of the peak-dip-hump structure indicated (i) a doping-independent boson energy and (ii) a significant oxygen isotope effect (Lee *et al*., 2006). An advantage of this study is that it was a local probe, and thus the local gap energy (which changes significantly with location in most STM studies of Bi2212) could be subtracted off to determine the local boson energy. A disadvantage of this analysis was that the boson energy was not associated with the dip energy scale as in other studies, but rather with a maximum in the derivative $(\mathrm{d}^2I/\mathrm{d}V^2)$ spectrum (which corresponds to an energy intermediate between the dip and hump energies). The physical significance of this alternate energy scale is not apparent, since there is no feature in the raw $\mathrm{d}I/\mathrm{d}V$ data at this energy.

One mysterious fact concerns the doping independence of the nodal kink energy mentioned above. From the Feynman diagram in Figure 11, this energy should be $\Delta + \Omega$ (where Δ is the gap value at the antinode), but Δ is known to be a strong function of doping. This requires Ω to have an opposite doping dependence to compensate. There is no evidence that this occurs for phonons, but this would occur in the spin case for underdoped materials (with Ω and Δ having opposite doping dependences (Eschrig, 2006)). A way out is to assume forward (small $\mathbf{q}$) scattering (Kulic and Dolgov, 2005) in Figure 11 instead (so that at the node Δ reduces to zero), but this is not consistent with the $\mathbf{q}$ dependence of the above-mentioned phonons (or the spin fluctuations for that matter).

Of course, one could argue that all of these results are suspect in that they implicitly assume Figure 11, which is a lowest-order result (and thus inherently assumes a Migdal approximation). It was already mentioned that such an approximation can be suspect for spin fluctuations. Moreover, some authors have advocated that the hump is a polaron effect, with the hump maximum representing multiple phonon shake offs (Shen *et al*., 2004). In the spin case, the ultimate strong coupling picture is that advocated by Anderson and coworkers based on the RVB picture (Anderson *et al*., 2004).

6 RVB THEORY

This concept was proposed early on by Anderson (1987). Anderson assumed that quantum fluctuations (due to the low spin $S = 1/2$ of the Cu d^9 ion and the quasi-two dimensionality of the crystal structure) would melt the Néel order typically associated with Mott insulators. He proposed that the resulting state would be a liquid of spin singlets. As a given singlet involves coupling two of the copper ions, and each copper ion is surrounded by four other copper ions, then each bond can be either part of a singlet or not (Figure 13). Therefore, each bond can 'resonate' between being part of a singlet or not, hence the notation 'resonating valence bond' (after the work of Pauling, where in benzene, say, one can think of each carbon–carbon link as resonating between a single electron and a double electron bond). Now, imagine doping a hole into such a configuration. Since each copper ion in the undoped case participates in a singlet, then one singlet is broken. This leaves a free chargeless spin (denoted as a *spinon*) and a spinless charged hole (denoted as a *holon*). This implies the presence of spin-charge separation. The jury is still out on this particular question. In one dimension, spin-charge separation with its resulting non-Fermi liquid characteristics do occur (and is one of the major motivations for those pursuing models based on stripes). But to date, there is no exact answer to this question in two dimensions.

Regardless, Anderson's idea had a profound influence on the field. It emphasized that the cuprates should be thought of as doped Mott insulators, that a 'single-band'

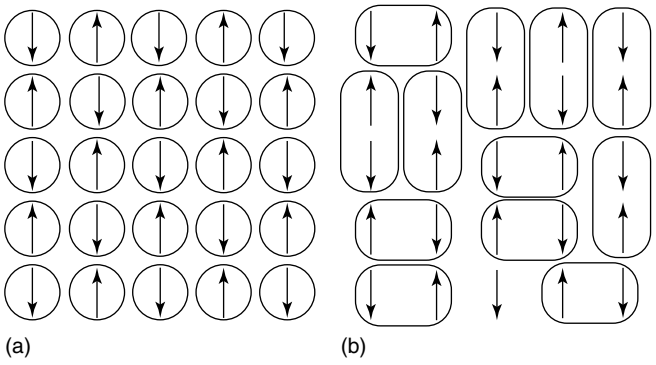

Figure 13. Néel lattice (a) versus RVB (b). The RVB state is a liquid of spin singlets. Circles are copper sites, arrows represent spins, and ovals are spin singlets.

approximation should be adequate, and that non-Fermi liquid effects would be pronounced. It also suggested a novel mechanism for superconductivity. Once the doped holes became phase coherent (at temperatures below the phase coherence temperature, which is roughly proportional to the doping), then spin-charge recombination would occur. The resulting charged singlets would be superconducting because of bose condensation of the holons. Although the original prediction for this superconducting state was s wave, it was realized by several groups within a year that the actual lowest free-energy state would be d wave (Kotliar and Liu, 1988; Zhang, Gros, Rice and Shiba, 1988).

One interesting prediction of this theory is that the pairing (spin) gap would be maximal at zero doping and then decay approximately linearly with doping (the $J_{\text{eff}} = J - tx$ relation mentioned before). On the other hand, the superconducting order parameter would initially be linear in doping, reach a maximum, and then follow the pairing gap for overdoped materials, forming the famous superconducting dome (Figure 14). The resulting phase diagram (also shown in Figure 14) reveals four different states, a superconducting state, a strange metal phase, a Fermi liquid, and a spin gap phase (Nagaosa and Lee, 1992). The RVB spin gap was probably the first prediction for the subsequently observed pseudogap phase. In RVB theory, the pseudogap phase corresponds to a spin singlet state (with its resulting spin gap) but no phase coherence in the charge degrees of freedom. One of the interesting ideas to emerge from this was an explanation for transport in this phase, which reveals a metallic behavior for in-plane conduction, but an insulating behavior for conduction between the planes. In the RVB picture, the metallic behavior is due to the fact that the holons can freely propagate. But to tunnel between the planes, the holons and spinons must recombine to form physical electrons, and this costs the spin gap energy, thus one obtains insulating like behavior for the c-axis conduction (Lee, Nagaosa, Wen, 2006). This 'gap' has now been directly seen in c-axis infrared conductivity data (Homes *et al*., 1993).

At the mean-field level, the RVB physics is relatively well understood. Going beyond mean-field theory has been a challenge. One way is to note that when considering a $t - J$ model, the RVB ground state corresponds to a projected BCS wave function (the projection designed to remove all d^{10} copper sites, which would be at infinite energy in the infinite U limit). One can perform variational Monte Carlo simulations with such a wave function. At zero doping, this state is energetically competitive with the true (Néel) ground state (there is no sign problem in the undoped case, so extensive Monte Carlo simulations have been performed). Though no proof exists for finite doping, we know that the Néel state is rapidly destroyed with doping, and it is anticipated that the RVB state, if anything, will be more

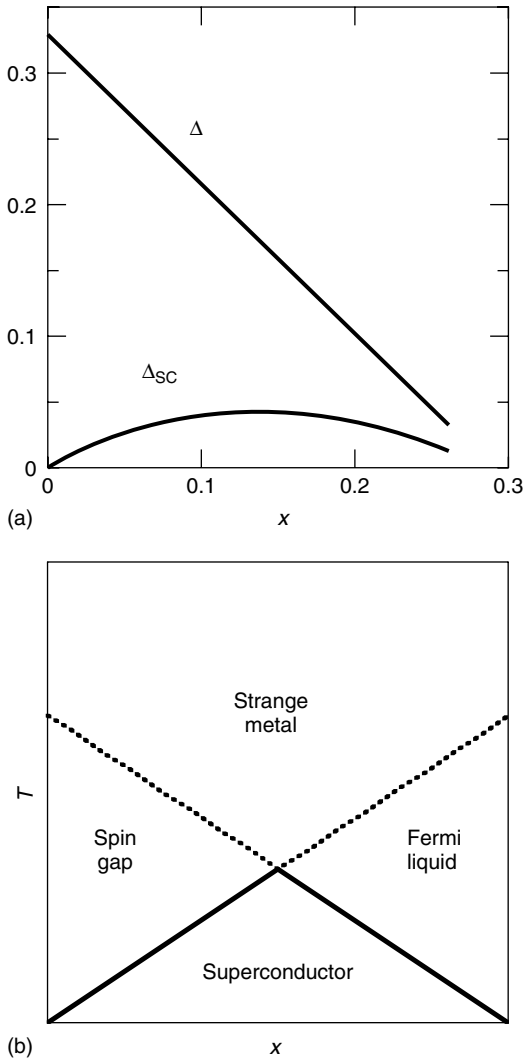

Figure 14. Spin gap, Δ, and superconducting order parameter, Δ_{SC}, as a function of doping from RVB theory (a). RVB phase diagram (b).

competitive once the magnetism disappears. Recent advances in Monte Carlo technology has allowed other quantities besides the group state energy to be calculated. Paramekanti, Randeria, and Trivedi have exploited this to calculate a variety of properties at zero temperature, in particular, the doping dependence of the spin gap, the superfluid weight, the quasiparticle residue, the Drude weight, and the nodal Fermi velocity (Paramekanti, Randeria and Trivedi, 2001). The results are in favorable agreement with experiment. Extending these studies to finite temperature and excited state properties remains a challenge for the future. As an aside, one can also perform a partial projection. This is the basis of the gossamer superconductivity theory of Laughlin (2006), that predicts a ghostly form of superconductivity for small dopings.

The other approach (Lee, Nagaosa, Wen, 2006) has been to exploit the same quantum field theoretic treatments used for heavy fermion materials (the slave boson approach for the Kondo lattice). The spinons and holons are not physical objects, and there is an arbitrary phase relation between the two. This introduces a U(1) gauge degree of freedom in the problem (that cancels for the physical electron). Associated with this is a vector gauge field that acts to satisfy the constraint that the spinon and holon currents balance (the scalar component of the field satisfying the no double occupation constraint). In this formalism, the mean-field state is the saddle point of the resulting Lagrangian. Fluctuations are represented by the quadratic terms associated with the gauge fields. This theory has had some successes (some of the calculated properties qualitatively follow the doping trends found later by the variational Monte Carlo simulations). In particular, it gave the first understanding of how the Fermi surface could be large for hole doped materials (scaling like $1 - x$), whereas the quasiparticle, Drude, and superfluid spectral weights scale as x (Kotliar, 1995). In essence, the Fermi surface remains large as the doping is reduced, but its spectral weight continuously disappears, so it ends up vanishing, much in the way of the Cheshire cat in Alice in Wonderland. This picture is more or less consistent with photoemission and optics data.

There were problems with the U(1) theory, though. Such a theory predicted that the linear T term in the superconducting penetration depth (due to thermally excited carriers near the d-wave node) scales as x^2, which has not been observed. This led Patrick Lee and collaborators to look at an SU(2) generalization (Lee, Nagaosa, Wen, 2006). In the undoped case, the presence of a down spin on a copper site is equivalent to the absence of an up spin (because in the undoped case, every copper site has exactly one spin). As Affleck *et al*. point out (Affleck, Zou, Hsu and Anderson, 1988), this implies that the U(1) symmetry previously mentioned expands to an SU(2) symmetry in the undoped case. Connected to this is the fact that in the undoped case, the d-wave spin pairing state is quantum mechanically equivalent to the so-called π flux phase where currents flow around a copper plaquette (Figure 15), these two states being connected by a rotation in particle–hole space. Obviously, this SU(2) symmetry is reduced to U(1) upon the introduction of holes, but the fluctuations implied by this enlarged symmetry group are certainly relevant. In this SU(2) picture, the above-mentioned problem is 'fixed' (the linear T term in the penetration depth become roughly doping independent (Wen and Lee, 1998)), and in such a formalism, the pseudogap phase can be thought of as a state that fluctuates between a 'superconducting' direction and a 'flux phase' direction. In other words, the pseudogap phase is a fluctuating mother phase, from which various long-range ordered phases emerge

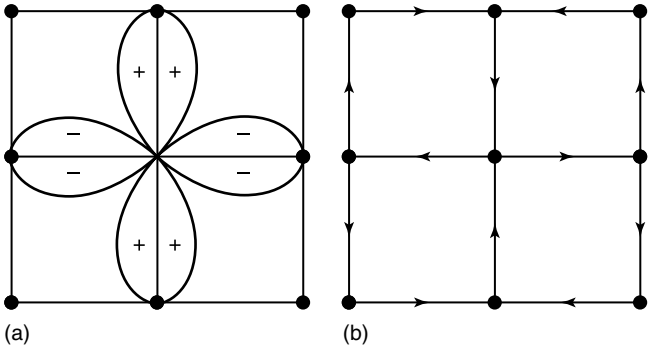

Figure 15. Two RVB states that are equivalent at zero doping: d-wave spin pairing state (a) and π flux state (b). Dots are copper ions and arrows are bond currents.

at lower temperatures (magnetic and spin glass states at low doping, superconductivity at intermediate doping). Note that the flux phase state is an orbital current phase, and is related to the d-density wave state that has been advocated by others as a phenomenological approach to the pseudogap phase (Chakravarty, Laughlin, Morr and Nayak, 2001).

This formalism also gives some idea into the existence of a Nernst effect above T_c (Xu *et al*., 2000). In normal metals, the Nernst effect (a transverse voltage generated by a thermal gradient) is small due to approximate particle–hole symmetry. But in superconductors, it can be very large in the presence of unpinned vortices (whose flow due to the thermal gradient generates a transverse voltage). Surprisingly, in cuprates, this Nernst effect extends significantly far above T_c, implying the existence of vortices well above T_c. But we know the superconducting gap is large, so how can such vortices be energetically favorable? In the SU(2) picture, this occurs since the vortex core is the pseudogap phase itself (rather than some gapless normal state) (Lee, Nagaosa, Wen, 2006). This pseudogap, in fact, has been seen in the vortex core of superconducting samples by STM measurements (Renner *et al*., 1998).

One issue with these types of theories is that they predict certain topological excitations associated with the gauge fields that have yet to be seen by experiment. Until they are, there will always be doubts about such approaches, since they are difficult to employ and the gauge fluctuation expansion is not well controlled, a common bane of strong coupling theories.

On more general grounds, one can ask how different these strong coupling approaches are from the more 'weak coupling' approaches discussed earlier. A famous debate has arisen on this subject, with Laughlin claiming that RVB and spin fluctuations represent two different limits of the same underlying theory (Laughlin, 1998), whereas Anderson has strongly differed (Anderson, 1997). As we pointed out earlier, there is one significant difference between these two

types of approaches. The spin fluctuation based approaches assume antiferromagnetic fluctuations, whereas in RVB, the fluctuations are singlet in character. It is somewhat surprising that this fundamental distinction has yet to be definitely cleared up by experiment.

7 ALTERNATE MECHANISMS

Space prohibits a detailed summary of the countless theories that have been proposed in the context of cuprate superconductors. But in this section, those of some note will be mentioned, especially in connection to what was discussed in the preceding text. This section (and article) is then ended with a brief discussion of the 'phonon' question.

The SO(5) approach of Zhang and collaborators (Demler, Hanke and Zhang, 2004) is similar in spirit to the SU(2) approach just mentioned. Instead of fluctuating between a flux phase and a superconducting phase, one fluctuates between the two known ground states (antiferromagnetism and superconductivity). The minimal group which contains these two order parameters is SO(5) (the 'five' being the real and imaginary values of the superconducting order parameter, and the three spatial components of the Néel vector). SO(5) has 10 generators, 4 of them being the charge operator and the 3 spin components, the other 6 are so-called π operators that connect the superconducting and Néel sectors of the theory. These operators, acting on the superconducting ground state, create the previously mentioned (π, π) resonance – that is, this resonance can be thought of as an excited triplet pair state with center of mass momentum (π, π). In the SO(5) case, though, this resonance is a property of the particle–particle channel, and only appears in neutron scattering because of particle–hole mixing in the superconducting state. This theory thus naturally explains why the resonance is only seen below T_c, and why its doping and temperature dependences scale with the superconducting order parameter (a property which does not obviously follow from the RPA calculations previously discussed). It also predicts that the vortex core is antiferromagnetic (Arovas, Berlinsky, Kallin and Zhang, 1997) and that charge modulation effects seen in tunneling for underdoped samples are from a checkerboard pair density wave state (Chen *et al*., 2002) (as opposed to stripes). There are some issues connected with this theory, though. The (π, π) resonance in this theory is an antibound state, as opposed to RPA where it is a bound state. Available data are much more consistent with the latter, as the resonance energy is less than 2Δ (that is, it lies below the particle–hole continuum rather than above (Tchernyshyov, Norman and Chubukov, 2001)). Moreover, although the theory incorporates the fact that the undoped material is an antiferromagnet, it does not take into account the fact that it is a Mott insulator (where the charge excitations are strongly gapped). To correct this obvious deficiency, a modified theory known as *projected SO(5)* has been developed, and the reader is referred to the literature for a discussion of this technique and how it addresses spectroscopy data like photoemission in the low doping regime (Zacher, Hanke, Arrigoni and Zhang, 2000). Space also prohibits a discussion of other 'preformed' pairs scenarios, such as the QED_3 theory of Franz and Tesanovic that advocates that the pseudogap phase is a phase disordered superconductor characterized by a proliferation of vortexlike excitations (Franz and Tesanovic, 2001).

The π flux phase mentioned in the context of RVB theories is an orbital current phase with an associated wave vector of (π, π). Such a phase is characterized by point nodes, that have been recently inferred as the $T = 0$ ground state of the pseudogap phase by thermal conductivity (Sutherland *et al*., 2005) and more recently photoemission data (the latter directly imaging the nodes (Kanigel *et al*., 2006)). On the other hand, there is no evidence from photoemission that the pseudogap (at least the low-energy one associated with the leading edge of the ARPES spectrum) has a finite $\mathbf{q}$ vector associated with it. In fact, current ARPES data are consistent with the pseudogap being tied to both the Fermi surface and to the Fermi energy, as would be expected for a $\mathbf{q} = 0$ state (a superconductor is a $\mathbf{q} = 0$ state, since the center of mass momentum of the pair is zero). But the π flux phase state is not the only orbital current phase that has been proposed. Varma has argued that when one reduces from the three-band model (copper $d x^2 - y^2$ orbital and oxygen p_x and p_y orbitals) to the commonly employed single-band model (the antibonding mixture of the copper and oxygen states), one has thrown out the baby with the bathwater so to speak (Varma, 2006). He believes a complete theory must keep all of these degrees of freedom. Although a discussion of this important topic would take us far outside the bounds of this review, it should be noted that optics data have revealed changes in spectrum when passing through T_c which extend up to several electronvolts (Rübhausen *et al*., 2001). If these degrees of freedom are important for superconductivity, then indeed neglecting higher-energy degrees of freedom could be dangerous. In Varma's theory, a unique orbital current phase emerges because of a nontrivial (Berry) phase involving the three different orbitals. This shows up in the antibonding band at the Fermi energy as an orbital current which flows in the subplaquette formed by a copper ion and its surrounding oxygen neighbors (Figure 16). Since the structure is based on the unit cell itself, it is a $\mathbf{q} = 0$ state. Originally, the theory had a current pattern such that would generate magnetic reflections for diagonal aligned Bragg vectors (Figure 16b). These were searched for by neutron scattering and not found. A related circular dichroism experiment was performed in photoemission by Kaminski *et al*. (2002) and found a

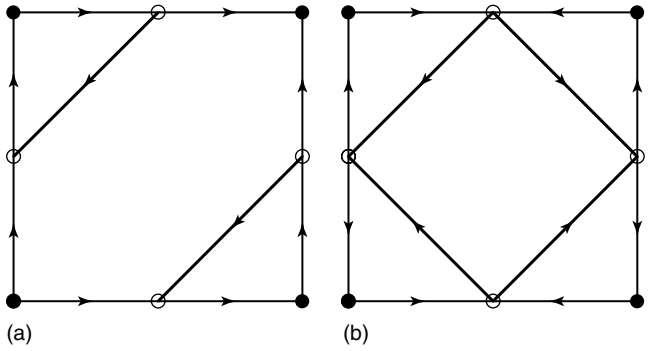

Figure 16. Two orbital current patterns proposed by Varma. Solid dots are copper ions, open dots are oxygen ions, and arrows are bond currents. The pattern in (a) has been used to interpret recent polarized ARPES and neutron results in the pseudogap phase.

dichroism shift along the $(\pi, 0)$–(π, π) direction (not yet reproduced by other groups, though). To account for this, Varma rotated his current pattern by 45° (Figure 16a). The resulting magnetic reflections would then be along the bond directions, and these were recently seen by neutron scattering (Fauque *et al*., 2006) (but again, not reproduced by other groups). Varma's theory also predicts nodes in the pseudogap phase, as has been recently inferred from experiment (as mentioned in the preceding text). Recently, a dichroism signal has been found by X rays that matches the ARPES one (Kubota, Ono, Oohara and Eisaki, 2006), but the claim was that the signal was structural, not magnetic, in origin.

Another inhomogeneous pattern, as mentioned before, is stripes. These patterns have been seen in several transition-metal oxides, and in the low temperature tetragonal (LTT) structural phase of doped lanthanum cuprate near $x = 1/8$ (Tranquada *et al*., 1995). As mentioned before, stripes give a natural explanation of the Yamada plot, have been proposed (in their dynamic version) as an explanation for the unusual hourglass-shaped spin dispersion seen in neutron scattering, and can account for various Fourier charge peaks seen in STM data (Kivelson *et al*., 2003). From a theoretical perspective, the advantage is that the quasi-1D nature of the stripes naturally yields spin-charge separation and its resulting non-Fermi liquid properties (which are more difficult to generate in homogeneous 2D models). The holes pick up their pairing gap by virtually hopping from the stripes to the undoped antiferromagnetic domains (Emery, Kivelson and Zachar, 1997) (even leg spin ladders having a spin gap). The much lower value of T_c as compared to the gap is determined by Josephson coupling of the stripes. The stripes picture has been important in focusing the physics community on the fundamental question of real space–based approaches as compared to the traditional momentum space–based approaches used in the past to address superconductivity. It emphasizes the role of inhomogeneity, which has been spectacularly seen in STM experiments (Pan *et al*., 2001). It provides a unique (quasi-1D) approach to the cuprate problem. But this approach has also raised a number of questions. A recent X-ray analysis of the $x = 1/8$ stripe phase in LBCO has found a smooth sine wave for the charge modulations, as opposed to the square wave picture of Figure 8 (Abbamonte *et al*., 2005). Charge modulation effects seen in STM are weak in intensity and, moreover, tend to trace out a checkerboard pattern (Hanaguri *et al*., 2004) as opposed to a stripe one (a checkerboard has been advocated for the spin pattern in doped LSCO as well in a recent neutron-scattering study (Christensen *et al*., 2004)). Even the large inhomogeneity effects seen by STM have been challenged by others (the group of Oystein Fischer typically does not observe them). Alternate explanations have also been given with reference to the STM Fourier peaks (McElroy *et al*., 2003) (for instance, similar ARPES autocorrelation studies are consistent with a joint density of states explanation for the Fourier peaks (Chatterjee *et al*., 2006)). But an interesting aspect of the stripes scenario is the possible coupling of lattice and charge/spin degrees of freedom. It is well known that certain phonons show anomalies that are thought to be connected with static stripes or their dynamic variants (Reznik *et al*., 2006).

Having mentioned the lattice, it is time to end this review with a discussion of the 'phonon' question. As mentioned earlier, it has been advocated that the peak-dip-hump lineshape seen in tunneling and ARPES is a strong polaron effect. Polarons are certainly prominent in other transition-metal oxides, such as manganites, and in fact were an integral part of the guiding principle that led Bednorz and Mueller to their original discovery. Whether they are present at optimal doping is an entirely different matter (the normal state actually being quite a good metal with well-developed screening as characterized by the 1-eV plasmon). And, as mentioned before, it has been advocated by several photoemission and STM groups that the strong coupling anomalies seen in those spectra are caused by phonons rather than magnetic excitations.

Of course, the one known thing in superconductivity is that phonons can definitely cause pairing. All finite frequency phonons contribute positively to the s-wave pairing channel (Bergmann and Rainer, 1973). Obviously, only some of them do for the d-wave channel. An advantage of the d-wave channel is the strong reduction in the direct Coulomb repulsion (due to the nodes in the pair wave function), but then again, we do not know of any s-wave electron–phonon superconductors which occur at 150 K, much less in the d-wave channel with its reduced coupling constant. So, it is a rather far stretch to believe that phonons can account for cuprate superconductivity. This does not mean

that they cannot be responsible for certain anomalies in experimental spectra, and even those authors advocating such are careful not to claim that phonons are solely responsible for superconductivity. But what is somewhat disturbing is the trend to fit the entire spectrum assuming phonons (or polarons) and ignore the underlying strong electron–electron interactions that presumably give rise to the various states (Mott insulator, d-wave superconductor) to begin with. It is difficult, of course, to properly treat all degrees of freedom (charge, spin, lattice), particularly for doped systems, and then one is faced with the 'everything but the kitchen sink' scenario for describing the material. In ^{3}He, it is a known fact that many degrees of freedom enter the various interactions, including the pairing one. But there, a spin fluctuation–based approach captures the fundamental essence of the problem. It is quite likely that such a spin fluctuation approach (or a strong coupling analog like RVB) will also capture the essence of the cuprate problem. But only time will tell.

ACKNOWLEDGMENTS

The author would like to thank many people for discussions that led to his thoughts as laid down in this review. A far-from-exhaustive list would include Phil Anderson, J C Campuzano, Andrey Chubukov, Seamus Davis, Matthias Eschrig, Steve Kivelson, Alessandra Lanzara, Bob Laughlin, David Pines, Mohit Randeria, Doug Scalapino, Z-X Shen, and Chandra Varma. The author acknowledges support from the US Department of Energy, Office of Science, under Contract No. W-31-109-ENG-38.

Magnetic Polarons

Stephan von Molnár[1] and Patricia A. Stampe[2]

[1] *Florida State University, Tallahassee, FL, USA*
[2] *Florida A & M University, Tallahassee, FL, USA*

1 INTRODUCTION

The concept of magnetic polarons is by now ubiquitous in any discussion concerning the physical properties of both concentrated and diluted magnetic semiconductors [1]. It is the goal of this brief overview to provide a historical perspective of the conceptual development of magnetic polarons based, in large part, on selected experimental findings. Our theme is to highlight the importance of the magnetic state of semiconductors in any discussion of their physical properties. The chapter describes the most important magnetic semiconductors, the europium and other rare-earth chalcogenides, having the NaCl- or thorium phosphide–type cubic structures, the mixed valence perovskites (see also **Ferromagnetic Manganite Films, Volume 5**), and the magnetically dilute II–VI and III–V semiconductors (see also **Ferromagnetic Semiconductors, Volume 5** and **Diluted Ferromagnetic Semiconductors – Theoretical Aspects, Volume 5**). The development of the concept of the magnetic polaron will be outlined and experimental evidence for the existence of this many-body state will be presented. This description borrows much from the well-studied dielectric polaron, in which the local environment around a charge defect is modified due to the effective dielectric susceptibility function. In a magnetic polaron the magnetic susceptibility plays a similar role. The discussion will end with a description of applications of these ideas to magnetically dilute oxides, where, however, experimental evidence is far more controversial.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

2 MIXED VALENCE PEROVSKITES (see also Ferromagnetic Manganite Films, Volume 5)

The most important early work on (diluted) magnetic semiconductors was the discovery by Jonker and van Santen (1950) (Jonker, 1956) that the $(La_{1-x}Ca_x)MnO_3$ manganite perovskites are ferromagnetic and conducting. Volger (1954) showed that $La_{0.8}Sr_{0.2}MnO_3$ displayed very large negative magnetoresistance which peaked near the Curie temperature, depending on the dopant concentration of manganese. As is now known, these effects have been reborn within the past 13 years (von Helmolt *et al*., 1993; Jin, McCormack, Tiefel and Ramesh, 1994) as 'colossal magnetoresistance' and have been the subject of massive research activities to this day. A

review by Coey, Viret and von Molnár (1999) gives a detailed account of work done up to the year 1999. The materials are very complicated, however, and spin and charge ordering, the Jahn–Teller distortion, as well as magnetic polaron formation may all contribute energetically over various portions of the phase diagram in describing the transport and spectroscopic properties of these materials. Direct evidence for the formation of small magnetic clusters in $LaMnO_3$ came from small angle neutron scattering (SANS) experiments and the concomitant anomalous volume lattice distortions observed by De Teresa *et al*. (1997).

To explain the origin of conductivity-induced ferromagnetism in $LaMnO_3$, Zener and others (Zener, 1951; Anderson and Hasegawa, 1955) proposed a spin-dependent electron transfer between 3d levels of the magnetic transition element ions. de Gennes, considering both antiferromagnetic superexchange and the Zener double exchange term (Zener, 1951), was able to describe in detail the magnetic phase diagram of the mixed valence manganites (de Gennes, 1960). He was also the first to point out that the presence of localized carriers results in a large deformation of the magnetic environment provided by the Mn spins. This realization and the suggestion of motion of the magnetic disturbance in the presence of a magnetic or electric field provided an initial guide for subsequent experimental observations (von Molnár and Methfessel, 1967). de Gennes' work foreshadowed the concept of the magnetic impurity state which was first investigated in detail by Kasuya and Yanase (1968), and independently by Nagaev (1974), for the case of the NaCl-type Eu chalcogenides. Before discussing Kasuya's model of the magnetic impurity state or bound magnetic polaron in detail, we summarize in the following paragraphs the physical properties of the rare-earth chalcogenides that led to the theoretical model.

3 RARE-EARTH CHALCOGENIDES

3.1 NaCl-type Eu chalcogenides (O, S, Se, Te)

The discovery in 1961 of the first ferromagnetic insulator, europium oxide (Matthias, Bozorth and Van Vleck, 1961), focused almost all research effort in the following years on the development and understanding of this general class of concentrated magnetic semiconductors, and interests in the perovskites abated. The europium chalcogenides are a particularly simple crystal structure, NaCl, and therefore are far more amenable to both experimental and theoretical analysis. It might be mentioned, parenthetically, that the observation of ferromagnetism in an insulating material was in itself a major theoretical challenge since conduction electrons, which normally provide the magnetic glue among magnetic ions, are in this case absent. Furthermore, the seven electrons having an $^8S_{7/2}$ ground state are very tightly bound to the atom core with a radial extent maximum at $\leq$0.1 nm (1 Å) (Friedman, Choppin and Feuerbacher, 1964). Kasuya (1970a) was the first to provide a theoretical basis for ferromagnetism that involved the virtual excitation of 4f electrons of the europium ion to a more extended d state which could overlap the wave function of the nearest-neighbor 4f electrons. The idea that (empty) 3d and 2s conduction band states could be partially filled by doping with trivalent rare earths (initially to produce impurity states and at more concentrated levels to lead to degenerate magnetic semiconductors), and thus increase the ferromagnetic transition temperatures was an almost natural consequence of the early findings (Matthias, Bozorth and Van Vleck, 1961). Experimental evidence was provided by the work of Holtzberg, Methfessel, Suits, and McGuire (1964). The figure of their data (Figure 1) gives dramatic proof of the interdependence of magnetism and carrier concentration or more broadly of magnetism and all other carrier-dependent physical properties in these concentrated systems.

3.1.1 Evidence for polaron formation

To the best of these authors' knowledge, the first reference to magnetic polaron formation was given by Heikes and Chen (1964) in a discussion concerning transport in sintered La-doped EuS that displayed a strong temperature-dependent peak in the resistivity near ferromagnetic order. Since this is an obscure reference, it is generally not recognized as part of the

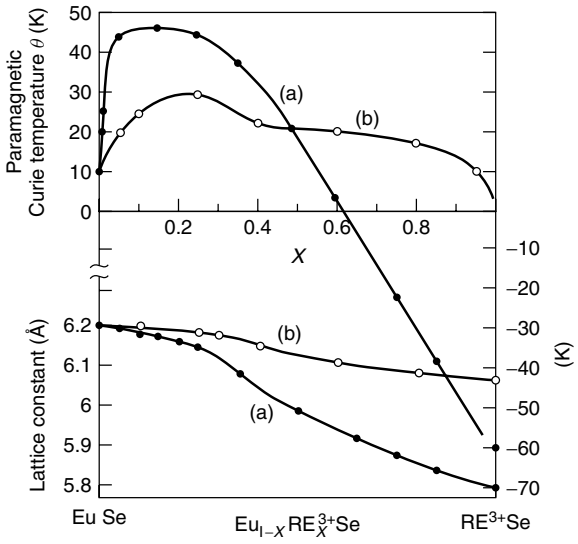

Figure 1. Variation of the paramagnetic Curie temperature and the lattice constant of EuSe with rare-earth substitution: (a) $Eu_{1-x}Gd_xSe$ and (b) $Eu_{1-x}La_xSe$. (Reproduced from Holtzberg *et al*., 1964, with permission from the American Physical Society. © 1964.)

history of the development of these ideas. Heikes suggested a model of impurity band conductivity in which the radius of the overlapping impurity wave function critically depended on magnetic order (magnetic polaron formation). The high resistivity near T_C results from a thermally activated hopping mechanism between occupied and unoccupied impurity sites. This suggestion is analogous to dielectric polaron formation and transport, discussed by, for example, Snyder *et al*. (1996), for mixed valence perovskites.

Figure 2 is a characteristic example of the effects observed and summarizes findings for a single crystal of EuS containing nominally 5% La. The observed experimental increase in resistivity above the paramagnetic Curie temperature θ_ρ ($\sim$35 K), which decreases with decreasing temperature as magnetic order increases, and the dramatic negative magnetoresistance clearly demonstrate that the transport properties depend on the magnetic state of the sample. These findings confirm the first detailed magnetotransport study in single crystal EuGdSe (von Molnár and Methfessel, 1967) and, combined with Hall and thermoelectric power measurements that point toward a mobility effect in EuGdSe, led to

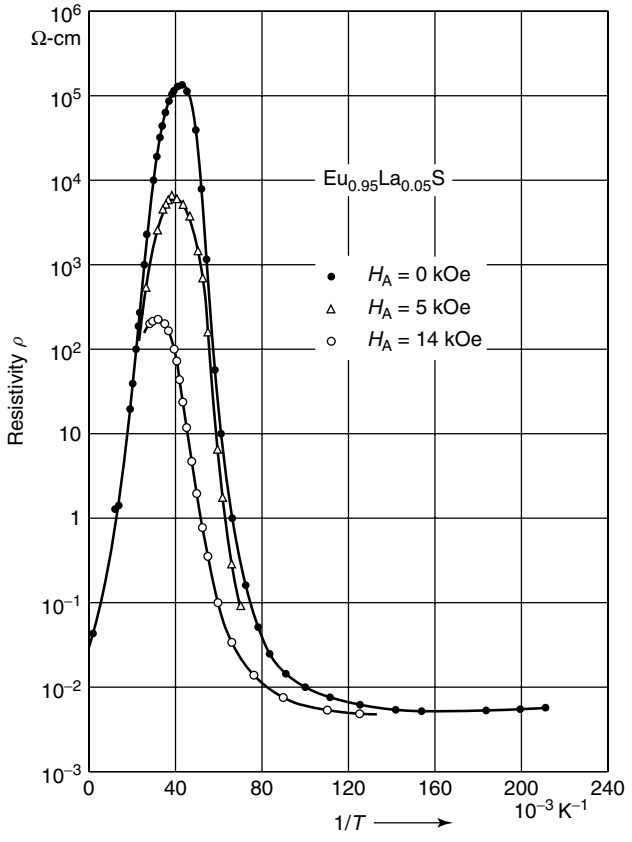

Figure 2. The peak in the resistivity of $Eu_{0.95}La_{0.05}S$ measured in various applied fields. (Reproduced from Methfessel *et al*., 1968, with permission from Springer-Verlag GmbH. © 1968.)

the conclusion that magnetic polarons are formed in these systems near and above T_C, only to be destroyed as ferromagnetic order develops. We quote verbatim from that paper:

'The possibility of reducing the kinetic energy by hopping to neighbors with parallel spin increases the effective ferromagnetic exchange interaction between neighboring $4f$ ions by an "indirect" type of double exchange mechanism resulting from the intra-atomic $4f-5d$ exchange. Therefore, we find here again the trapped electron surrounded by a polaron-like spin cluster. With decreasing temperature we expect the size of the polarons to increase and the accidental overlap of neighboring polarons to become more and more abundant. The proposed spin clusters, it should be pointed out, are not stationary in the lattice, but fluctuate by their interaction with phonons and spin waves. For temperatures below T_C, we visualize the electrons to move along chains of ferromagnetically aligned spin groups, which are interrupted by unordered spins. The decrease in the number of unordered spins with temperature is a function of the reduced (i.e., normalized) magnetization, and results in the observed resistivity decrease below T_C.'

It is to be noted that this description applies to many of the physical effects that will be discussed presently. In particular, the suggestion of magnetic phase separation plays an important role in theories of the metal insulator phase transition in the perovskite manganites (Gor'kov and Kresin, 1998, 2004), and was first mapped out experimentally in a detailed neutron diffraction study by Wollan (1955). It has also been seen in tunneling microscopy (Fath *et al*., 1999), noise spectroscopy (Raquet *et al*., 2000; Merithew *et al*., 2000), and in many other techniques (von Molnár and Coey, 1998). An analysis of critical scattering near the ferromagnetic transition temperature in the Eu compounds by von Molnár and Kasuya (1968) gave further credence to the magnetic polaron model. Critical scattering, first discussed by de Gennes and Friedel (1958) and later elaborated by Fisher and Langer (1968), was unable to explain the magnitude and width in temperature of the observed effect. Since the scattering amplitude depends on the correlation of spin fluctuations with respect to the Fermi wavelength of electrons in metals or degenerate semiconductors, larger objects, the magnetic polarons, were invoked as an explanation.

Other than the transport properties already mentioned, experimental evidence for magnetic polarons in concentrated magnetic semiconductors came from optical studies, reported first by Busch, Streit and Wachter (1970), in which they studied the emission and excitation spectrum of the photoluminescence of insulating EuTe, an antiferromagnet. These authors found that an observed increase in the luminescence intensity with decreasing temperature could be accounted for by the formation of magnetic polarons. The physical idea was that the polaron would shrink the wave function, and thereby

increase the probability of recombination. These authors also discovered that applying a large magnetic field reversed this process. The intensity became much smaller, presumably because the magnetic polaron was no longer bound, thereby reducing the probability of recombination.

3.2 Thorium phosphide–type rare-earth chalcogenides

von Molnár and colleagues (von Molnár, Holtzber, McGuire and Popma 1972; von Molnár and Holtzberg, 1973; von Molnár, Briggs, Flouquet and Remenyi, 1983; Washburn *et al*., 1984) studied the transport properties of $Gd_{3-x}v_xS_4$. Here v means vacancies that can be considered as donor dopants. The end member Gd_2S_3 is an antiferromagnetic insulator, whereas Gd_3S_4 is a ferromagnetic metal. Principal results are shown in Figure 3, where the logarithm of the resistivity at various fields and temperatures is presented. The main result is that while resistivity rises without bound with decreasing temperature at zero and low magnetic fields, a field of approximately 3.2 T transforms the material into a metal with a resistivity that is independent of temperatures below 10 K. The study by Penney,

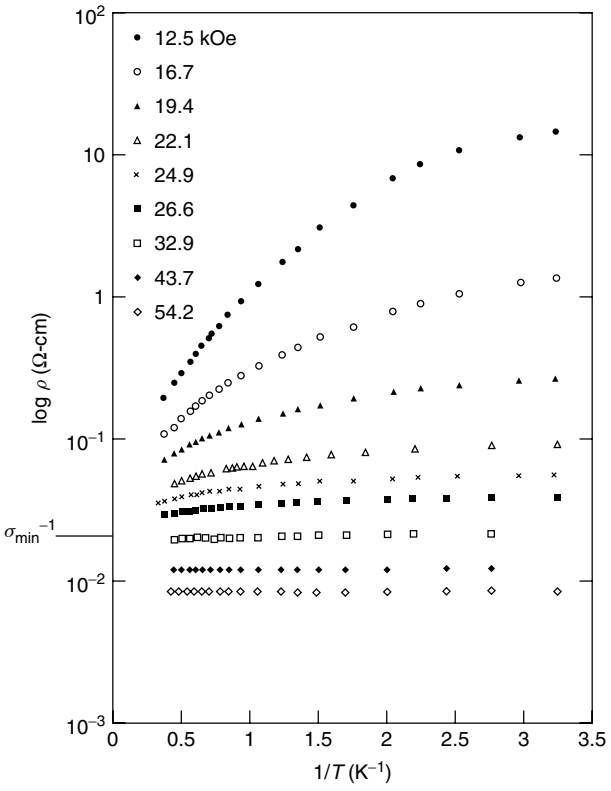

Figure 3. Temperature dependence of the magnetoresistance of $Gd_{3-x}v_xS_4$. (Reproduced from von Molnar *et al*., 1983, with permission from the American Physical Society. © 1983.)

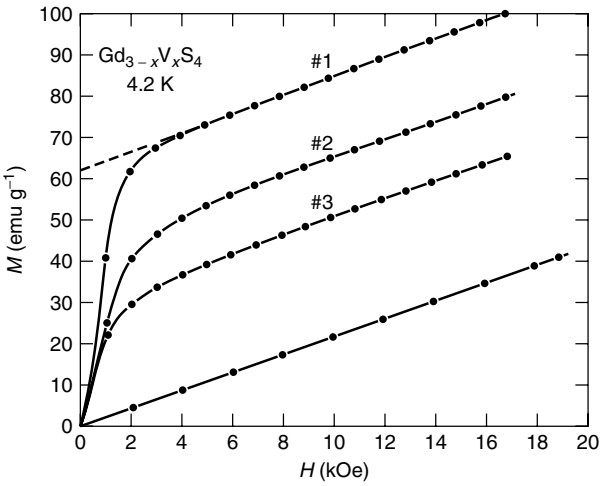

Figure 4. Field dependence of magnetization for $Gd_{3-x}v_xS_4$ for samples of varying carrier concentration. (Reproduced from Penney *et al*., 1974, with permission from the American Institute of Physics. © 1974.)

Holtzberg, Tao and von Molnár (1974) of the magnetic properties of these compounds provided the first magnetic proof that magnetic polarons in this otherwise antiferromagnetic material do exist. These results, given in Figure 4, show the magnetization of several samples with various carrier concentrations as a function of the applied magnetic field at 4.2 K. The significance of these data is that the pure material without any carriers (lowest curve) shows a magnetization rising linearly from zero with the field, as would be expected for a canting antiferromagnet, whereas with increasing electron concentration the extrapolated slope of magnetization versus field to zero field has a positive intercept on the magnetization axis. This remnant ferromagnetic component represents the polaron.

Finally, we again emphasize that the material undergoes a magnetic field–driven insulator-to-metal transition (Washburn *et al*., 1984), demonstrating, once again, that the electron, bound principally by magnetic interactions, can become a free carrier if the magnetic state of the lattice becomes similar to that of the polaron. A detailed study by Shapira, Foner, Reed and Oliveira (1972) in defect doped EuTe (also an antiferromagnet insulator) had arrived at this conclusion independently.

4 THE POLARON MODEL

In this section, we describe the polaron model originally envisioned to account for experimental observations in Eu chalcogenides, but also applicable with minor modifications to any magnetic system in which the magnetic species with moment $\vec{S}$ may be thought of as localized and interacting with the spin, $\vec{s}$, of an electron. Magnetic semiconductors

are interesting because this exchange coupling gives rise to an extraordinarily large Zeeman splitting expressed in the mean-field approximation as

$$E = g^* \mu_B \vec{s} \cdot H + 2J\vec{s} \cdot \left\langle \vec{S} \right\rangle \tag{1}$$

where g^* is the spectroscopic splitting factors for the carriers, μ_B is the Bohr magneton, and H is the applied magnetic field. $\langle S \rangle$ is the average value of the local moments over the region occupied by the band electrons. The second term of equation (1) can produce enormous splitting, amounting to fractions of an electron volt in Eu compounds below the magnetic ordering temperature and as large as 10 meV T^{-1} in (paramagnetic) diluted magnetic semiconductors. However, when the electronic states are not extended, the exchange J can lead to an additional localization beyond the normal Coulomb binding and correlations observed in nonmagnetic semiconductors. In an antiferromagnet (a paramagnet is much the same), this can lead to the formation of 'ferromagnetic' clusters – the magnetic polarons (Kasuya and Yanase, 1968; Dietl and Spalek, 1982; Heiman, Wolff and Warnock, 1983).

As has already been mentioned, Zener (1951) and de Gennes (1960) introduced spin-dependent electron transfer and spin polarons, respectively, to account for conductivity-induced ferromagnetism in $LaMnO_3$. Here we present Kasuya's arguments for the stability of the spin polaron (Kasuya, 1970a; Coey, Viret and von Molnár, 1999). It is assumed that a single electron or hole is introduced into an otherwise antiferromagnetic or paramagnetic lattice. In the absence of defects or impurities, the differential free energy ΔF_f, of a spherical polarized cluster in this background may be expressed as

$$\Delta F_f = \frac{E_0}{\gamma^2} - \frac{J}{2\gamma^3} \tag{2}$$

where $E_0 = (\pi^2 h^2 / 2ma^2)$, $\gamma = R/a$ and a is defined by the equation $4\pi a^3 = 1/N_{Eu}$. Here, we are specifically addressing the case for Eu chalcogenides, in which a magnetic Eu spin sits at every lattice site, and N_{Eu} is the number of Eu^{2+} ions per unit volume. Minimizing this free energy with respect to the radius, R, results in a nonphysical solution with $R \to 0$ or ∞. A more realistic model introduces the additional energy term found in equation (3) due to the Coulomb attraction of an electron to an oppositely charged center:

$$\Delta F = \Delta F_f - \frac{e^2}{\varepsilon R} \tag{3}$$

Of course, this is the situation most often encountered in bulk semiconductors, since the (concentrated) magnetic semiconductors are insulators, unless doped, and the dopant acts as an attractive center, just as it would in any ordinary semiconductor. Under these conditions, minimization with respect to R yields a stable configuration, and Kasuya referred to this as the bound magnetic polaron or magnetic impurity state. Although the second term in equation (3) describes a simple Coulomb attraction, a screened Coulomb or other inverse R dependence should also lead to a solution at finite R. More complex descriptions may be appropriate when the Coulomb attractive term is weak or absent, such as the recent developments in (Cd,Mn)Te (Jaroszynski *et al*., 2006). Below the Neél temperature of an antiferromagnet, the polarons will not move easily in the presence of an electric field, since they have to drag their polarization cloud along, which leads to a large effective mass (diffusive motion) (Kasuya, 1970b; Wolfram and Callaway, 1962) or localization. It also becomes clear how an applied magnetic field can produce an insulator–metal transition. The magnetic contribution to the localization comes about from the difference between the antiferromagnetic or paramagnetic order of the host and the ferromagnetic order of the polaron. In a magnetic field, as the sublattice develops an ever increasing net magnetization, this energy difference decreases and ultimately the carrier becomes unbound. If there are defects present, this polaron, which might be describable as a heavy but band-like particle moving diffusively (Kasuya, 1970b; Wolfram and Callaway, 1962), will typically be bound to defects such as the Coulomb potential described earlier. Transport under these conditions occurs via 'hopping', which may also be magnetic field dependent. The previous description is in the limit of small carrier concentration in a concentrated magnetic lattice. These ideas, however, may be applied also to situations where carrier concentration is large, but the magnetic lattice is diluted. As will be seen (Ohno *et al*., 1996), a large polaron results. The type of transport will still be stipulated by the proximity of the Fermi energy with respect to the mobility edge, a concept that also embraces the physical picture of percolating clusters more magnetically ordered and more conducting than the sublattice background.

5 II–VI DILUTED MAGNETIC SEMICONDUCTOR (see also Ferromagnetic Semiconductors, Volume 5)

The prototypical example of this class of semiconductors is CdTe doped with Mn (Mn^{2+} is a $^6S_{5/2}$ ion), which substitutes for Cd sites in this zinc blende structure. In this case, however, additional doping of, for example, In is necessary to provide carriers to this otherwise insulating system. Several magnetotransport studies have been interpreted in terms of magnetic polaron formation (Sawicki *et al*., 1986; Wojtowicz *et al*., 1986). A number of transport and concomitant magnetic studies made use of the fact that In:$Cd_{1-x}Mn_xTe$

is a persistent photoconductor in which, for suitably low temperatures, the carrier concentration may be varied continuously by temporary illumination, that is, the material may be photodoped (Terry *et al*., 1992b). Over the concentration range between 4×10^{16} and $2 \times 10^{17}\,\mathrm{cm}^{-3}$, in a regime where low-temperature transport occurs by hopping, the conductivity changes from a $1/T^{1/2}$ law, characteristic of variable range hopping with Coulomb interactions to simple activation, $1/T$, as temperature is decreased. This 'hard gap' of inaccessible states was interpreted as the difference between unrelaxed magnetically disordered empty states and the magnetically relaxed state, which occurs after the electron has hopped and formed a bound magnetic polaron. Applying a large magnetic field eliminates the energy difference between magnetically disordered and ordered states and the $T^{1/2}$ law is recovered (Terry, Penney and von Molnár, 1992a). The most direct evidence, however, comes from a number of ingenious optical studies (Dietl and Spalek, 1982; Heiman, Wolff and Warnock, 1983; Harris and Nurmikko, 1983; Awschalom *et al*., 1985; Awschalom, Warnock and von Molnár, 1987). Dietl and Spalek (1982) and Heiman, Wolff and Warnock (1983) independently developed theories introducing magnetic polarons to explain spin-flip Raman data, with finite spin-flip energies even at zero applied magnetic field. They concluded that the effective field is provided by the fluctuating magnetic polaron. More recent Raman studies of the Eu chalcogenides and their interpretation utilizing polaron concepts have been reported by Cooper *et al*. (Rho *et al*., 2002a,b; Snow *et al*., 2001).

Some of the most exciting developments in the study of magnetic polarons have, however, employed time-resolved techniques. Polaron formation has been studied by observations of the time evolution of the polaron-binding energy, on picosecond timescales, in transmission and luminescence (Harris and Nurmikko, 1983; Awschalom *et al*., 1985). A remarkable innovative experiment by Awschalom, Warnock and von Molnár (1987) succeeded in direct observations of spin dynamics responsible for polarons through time-resolved magnetic measurements. This elegant magnetic spectroscopy employs a planar DC SQUID as a detector to measure the statically and dynamically induced magnetization as a function of impinging radiant energy. Finally, this spectroscopy was employed to study polaron formation even in confined geometries (Awschalom *et al*., 1991). These results are shown in Figure 5. Samples were constructed of multiple quantum wells of (zinc-blende type) $Cd_{1-x}Mn_xSe$ confined by ZnTe barriers. These magnetic heterostructures are type II, that is, optically excited electrons are confined to the $Cd_{1-x}Mn_xSe$ layer and holes to the ZnTe layer. The magnetization induced by electrons optically excited from the valence to the conduction bands of the heterostructure are then monitored as a function of excitation energy, both statically and dynamically. Here we focus on the static results. For an excitation energy of the impinging circularly polarized light in the vicinity of the quantum well ground state, a magnetic peak is observed for energies somewhat lower than the $n = 1$ quantum level. This is due to magnetic polaron formation. For energies lower than the polaron energy, the absorption is minimal.

Magnetization rises, however, with the onset of absorption into the impurity level at which polarons form. The subsequent decrease for higher energies is due to spin scattering, which results in a relaxation of polaron orientation and a much smaller net magnetization in a direction perpendicular to the pickup loop of the SQUID. It is to be noted that the polaron peak exists despite the fact that the bulk polaron radius is estimated to be approximately 9 nm, whereas the thinnest quantum well is only 1.8 nm wide. Clearly, the polaron can no longer be thought of as being spherical, but must by necessity, take on a pancake-like shape. The observed time-dependent polaron magnetization also deserves comment. It grows and decays at relatively long timescales, on the order of 400 ps, characteristic of spin lattice relaxation times. This means that this process leaves a magnetic imprint that lasts far longer than the lifetime of the photoexcited electron (femtosecond) which caused it in the first place.

6 III–V DILUTED MAGNETIC SEMICONDUCTORS (see also Ferromagnetic Semiconductors, Volume 5 and Diluted Ferromagnetic Semiconductors – Theoretical Aspects, Volume 5)

Following seminal work by Story, Galazka, Frankel and Wolff (1986), who discovered ferromagnetism in PbSnMnTe diluted magnetic semiconductors, III–V diluted magnetic semiconductors were first produced in InAs and GaAs (Munekata *et al*., 1989). Although transition-metal (TM) ions have by now been introduced into many additional members of the III–V semiconductor family, in this discussion, we confine ourselves to InMnAs and GaMnAs, since these materials have been studied in the greatest detail and evidence for magnetic polaron formation exists.

The first evidence comes from an analysis of magnetotransport and magnetization in thin films of p-doped InMnAs close to the insulator–metal transition by Ohno *et al*. (1992). These authors observed an anomalous Hall effect which dominates Hall measurements for temperatures between ∼0.4 K and close to room temperature. Partially ferromagnetic order is observed below ∼7.5 K (Figure 6). The coexistence of remanent magnetization and unsaturated spins, as well as large negative magnetoresistance at low temperatures, was interpreted as being due to the formation of large magnetic polarons with average magnetic correlation lengths exceeding 10 nm. The measured hole concentration of $\sim 2 \times 10^{19}$ cm^{-3} implies that many electrons contribute to the magnetic cluster. A theoretical description of these large magnetic polarons in diluted systems was first advanced by Isaacs and Wolff (1987).

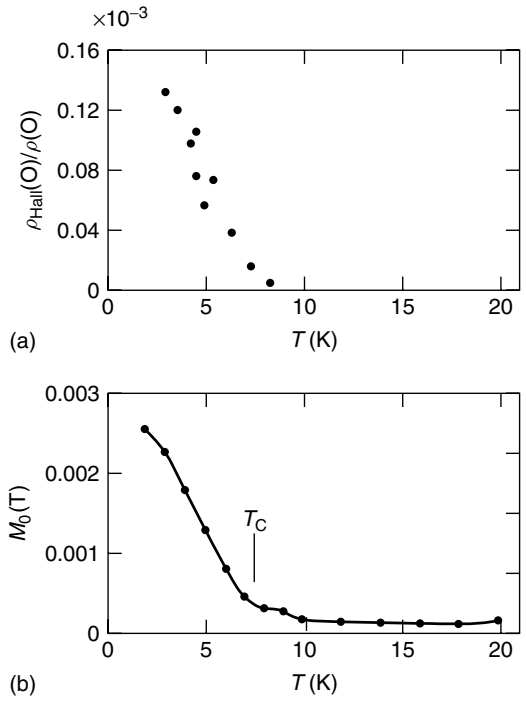

Figure 6. (a) Temperature dependence of the remanent part of Hall resistivity divided by the zero field resistivity of InMnAs. (b) Temperature dependence of the remanent magnetization of the film. (Reproduced from Ohno *et al*., 1992, with permission from the American Physical Society. © 1992.)

Other evidence comes from magnetic circular dichroism studies in GaMnAs by Beschoten *et al*. (1999). These authors show that the evolution of ferromagnetism in p-type GaMnAs can be separated into two distinct spectral contributions as a function of applied field depending on the excitation energy. A high-energy ferromagnetic and lower-energy antiferromagnetic signal is observed. The low-energy signal is attributable to antiferromagnetic exchange between holes and Mn^{2+} ions, which leads to a polaron cloud that forms below T_C.

The renaissance in studies of diluted systems following the discovery that GaMnAs can reach ferromagnetic transition temperatures in excess of 110 K (Ohno *et al*., 1996; Ohno, 1998, 1999; Furdyna *et al*., 2002; Ku *et al*., 2003; Maksimov *et al*., 2004) has also resulted in theoretical reexamination of magnetic polaron formation and transition to the ferromagnetic (conducting) state. In particular, a magnetic polaron model has been developed for purely insulating or highly resistive III–V materials, which often exhibit Mott variable range hopping at low temperatures, consistent with carriers localized in polarons (Wolff, Bhatt and Durst, 1996; Bhatt, Berciu, Kennett and Wan, 2002; Kaminski and Das Sarma, 2002; Durst, Bhatt and Wolff, 2002; Das Sarma, Hwang and Kaminski, 2003). The magnetic polaron percolation description assumes that the carrier density n_c is much lower than the impurity dopant density n_i. The carriers are localized in hydrogenic orbitals forming polarons. The polaron radius, r_H, depends on the dielectric constant, ε, and the effective mass m^* viz.

$$r_H = \varepsilon \left(\frac{m}{m^*}\right) a_0 \tag{4}$$

where a_0 is the Bohr radius, 5.3×10^{-11}m. The dopant impurities are assumed to be substitutional at the cation site. Magnetic exchange between the magnetic moment of the dopant impurities and the moment of the localized carrier results in ferromagnetic alignment of the impurity moments and a large effective moment that naturally depends on the impurity density in the cation site. The radius, r_P, over which the impurity moments are bound to those of the carrier, varies inversely with temperature, as (Bhatt, Berciu, Kennett and Wan, 2002; Das Sarma, Hwang and Kaminski, 2003;

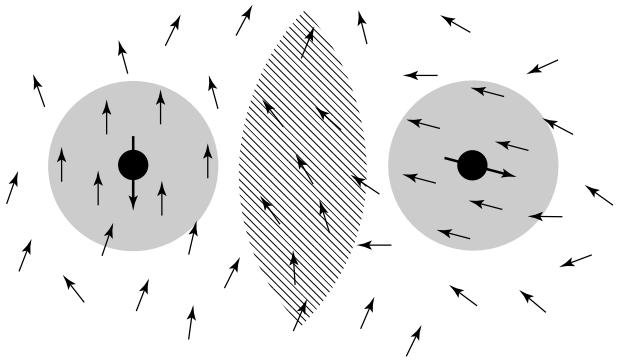

Figure 7. A schematic diagram showing the interaction between two bound magnetic polarons (gray circles). The large arrows represent impurity spins while the small arrows represent carrier spins. The lens-shaped shaded region indicates the region that is important for the interaction of the two polarons. (Reproduced from Kaminski *et al*., 2002, with permission from the American Physical Society. © 2002.)

Kaminski and Das Sarma, 2002)

$$r_{\mathrm{P}} = \frac{r_{\mathrm{H}}}{2} \ln\left(\frac{sSJ}{T}\right) \tag{5}$$

where J is the effective exchange constant. If the polarons are spaced sufficiently far apart, the magnetic exchange between polarons will be small, and the material will be paramagnetic. As the temperature decreases, the polaron radius increases, allowing overlap. Ferromagnetic exchange between neighboring magnetic polarons (Figure 7), the mechanism for which was detailed by Wolff, Bhatt and Durst (1996), results in bulk ferromagnetic ordering of the material.

Assuming the polarons to act as rigid spheres, percolation will be achieved when

$$r_{\mathrm{P}} \left(n_{\mathrm{c}}\right)^{1/3} = 0.86 \tag{6}$$

From this, an expression for the Curie temperature below which percolation (and magnetic ordering) is achieved can be obtained.

$$T_{\mathrm{C}} \approx sSJ \left(r_{\mathrm{H}}^3 n_{\mathrm{c}}\right)^{1/3} n_{\mathrm{i}}^{1/2} n_{\mathrm{c}}^{-1/2} \exp\left(\frac{-0.86}{\left(r_{\mathrm{H}}^3 n_{\mathrm{c}}\right)^{1/3}}\right) \tag{7}$$

No attempt has been made to compare the theoretical T_{C} with experimental values owing to the experimental difficulty in obtaining accurate values for n_{c} in highly insulating specimens as well as uncertainties in actual dopant concentration. In addition, as pointed out by Gor'kov and Kresin (1998), the assumption of a rigid sphere model should be modified owing to site correlation.

The magnetic moment as a function of temperature below T_{C} can be calculated on the basis of the number of impurity atoms contained within the percolating cluster, and yields concave $M(T)$ curves similar to those obtained in low carrier concentration samples of InMnAs (Ohno *et al*., 1992) and $Ge_{1-x}Mn_x$ (Park *et al*., 2002; Li *et al*., 2005). This model also explains the lower-than-anticipated magnetic moment observed in these III–V materials, since at a given temperature not all impurity atoms are within the percolating cluster and do not contribute to the observed ferromagnetic moment. The bound magnetic polaron picture has also been used, with some expansion, to explain some of the properties of the dilute magnetic oxides discussed in the following section.

7 DILUTE MAGNETIC OXIDES

Triggered by the prediction, in 2000 (Dietl *et al*., 2000), of room-temperature ferromagnetism in p-type ZnO doped with 5% Mn, considerable research has been focused on the development of dilute magnetic semiconductors based on wide-band gap oxides such as ZnO, TiO_2, and SnO_2 doped with small amounts of TMs. A large body of work already exists and has been reviewed elsewhere (Pearton *et al*., 2003a, 2004; Janisch, Gopal and Spaldin, 2005). Several overall trends have been revealed as follows:

1. *Lack of reproducibility*: Samples of nominally the same material prepared by different research groups often appear to have very different properties, ranging from paramagnetic to ferromagnetic.
2. *Anomalously large moments*: Some materials doped with small amounts of TM have been reported to have measured moments per dopant atom larger than that expected for the spin-only moment of the dopant atom (Fitzgerald *et al*., 2005; Ogale *et al*., 2003; Hong *et al*., 2005a; Hong, Sakai, Prellier and Hassini, 2005b). However, it should be noted that these large moments per impurity atom occur for TM concentrations of typically 1% or lower. This leads to very small sample moments on the order of 10^{-5}–10^{-4} emu, which are difficult to measure accurately. Also, small uncertainties in dopant concentration can lead to large uncertainties in the calculated moment per impurity atom.
3. *Decrease in moment with dopant concentration*: A general trend of reduced moment per dopant atom is observed as a function of increased TM dopant concentration (Ogale *et al*., 2003; Fitzgerald *et al*., 2005; Janisch, Gopal and Spaldin, 2005).
4. *High-transition temperatures*: Observed Curie temperatures are above room temperature. These transition temperatures are very high for such low magnetic dopant concentrations.

5. *Magnetism/carrier concentration*: Ferromagnetism has been reported in both conducting and insulating specimens. To our knowledge, there has been no convincing conclusive evidence of the relationship between magnetism and carrier concentration, which would be expected if the magnetic exchange is carrier mediated. In some cases, it has been observed that the addition of a donor codopant, such as lithium in ZnO (Lee, Jeong, Hwang and Cho, 2003), increases the magnetic properties of the material. In contradiction though, recent results show that H doping results in significant ferromagnetism but little change in carrier concentration (Lee *et al*., 2006).
6. *Substrate dependence*: A number of groups have shown that the magnetic properties of the thin films are strongly dependent on the substrate on which the material is grown. In general, the lowest quality film crystallinity gives the most magnetic films (Hong *et al*., 2005a; Hong, Sakai, Prellier and Ruyter, 2005c; Kaspar *et al*., 2005).
7. *Moment in d^0 systems*: There have also been reports of magnetism in ZnO films doped with Sc and in HfO_2, both materials with no intrinsic magnetism (Coey, Venkatesan and Fitzgerald, 2005a; Coey *et al*., 2005c).
8. *Anisotropy*: Several researchers have noticed a strong dependence of the saturation magnetization on the direction of the applied field (Coey *et al*., 2005b).

These features have led to a debate over whether the magnetism in these materials is truly intrinsic or extrinsic. In particular, the lack of reproducibility and giant moments has led to suggestions of the formation of secondary phases or contamination during sample preparation. For example, it has been shown that the ferromagnetic moment in bulk Mn:ZnO prepared by sintering (Sharma *et al*., 2003) can be explained by the formation of such ferromagnetic secondary phases (Kundaliya *et al*., 2004). Recently, Colis *et al*. have been able to detect secondary phases in Mn-doped ZnO via the presence of additional signatures in Raman spectroscopy data (Colis *et al*., 2005), even though X-ray data on the same sample showed a single phase material. The authors conclude that the observed ferromagnetism results solely from these secondary effects. There also exists the possibility of clusters of the ferromagnetic dopant occurring as seen in TiO_2:Co (Kim *et al*., 2002; Kennedy *et al*., 2004). It is clear therefore that detailed microstructural characterization must be done before analysis of the origin of ferromagnetism can be made. Although such measurements have been done for much of the data presented in the literature, secondary phases that could cause ferromagnetic signals at room temperature can be very small in size, and are close to the current measurement limitations. This makes it difficult to preclude definitely extrinsic sources of magnetism in these doped oxides.

In most experimental setups, starting materials and finished samples are handled numerous times by metal implements such as stainless-steel tweezers, which can transfer small amounts of ferromagnetic material to a specimen (Abraham, Frank and Guha, 2005). In addition, the growth environment (furnace, vacuum chamber) can contain amounts of magnetic impurities, which, unless great care is taken, can be transferred to the sample. Varying amounts of contamination could easily be a cause for the lack of reproducibility between research groups worldwide, and may explain the spread in reported results.

Despite these reservations, there has been a growing consensus that a number of these features can be explained using models based on magnetic polarons. Although the polaron percolation model described earlier appears to explain the doped III–V materials, it is not clear whether it can be applied equally well to the dilutely doped magnetic oxide materials described earlier. Owing to the large Curie temperatures observed in the oxides, there are few measurements of $M(T)$ and even of T_C with which to compare. Also, the magnetic oxides often exhibit moments higher than expected, rather than the lower moments predicted by the above model.

Defects are expected to play a key role in both the magnetic and transport properties of the doped magnetic oxides. In these materials, it is generally considered that the TM dopant cations substitute for the cation in the crystal structure. We let the symbol x, with values from 0 to 1, represent the degree of substitution in the cation site, that is, $Zn_{1-x}M_xO$ and $Ti_{1-x}M_xO_2$, where M is the TM dopant. It should be noted that while in ZnO the TM cation substitutes for a cation with a valency of 2 (Zn^{2+}), in TiO_2 and SnO_2, the TM cation substitutes for a cation with a valency of 4. Most TMs form ions with valencies of either 2 or 3. This means that when substitutional in either TiO_2 or SnO_2, oxygen vacancies will form in order to ensure charge neutrality of the crystal. Also, ZnO and SnO_2 show a tendency toward the formation of cation intersitials, further increasing the nonstoichiometry. In general, then, the chemical formula for these oxides should include the possibility of oxygen nonstoichiometry, that is, $Ti_xM_{1-x}O_{2-\delta}$. In this case δ is a representation of the defect concentration in the material.

Recently, Coey has expanded the polaron percolation model to incorporate conduction through the formation of a conducting impurity band at sufficiently high defect concentration in the oxides (Coey, Venkatesan and Fitzgerald, 2005a; Coey, 2005). It is assumed that the n-type carriers are localized at donor defect sites, and thus the polaron distribution is directly dependent on defect concentration and distribution. In the high dielectric oxides under consideration here, the polaron radius r_H can be on the order of several nanometers, since it is directly proportional to the dielectric constant of the material. This large polaron radius can

encompass hundreds of cation sites and thus a number of dopant sites.

At low defect concentrations the carriers are trapped and the material is insulating. As the defect concentration (and carrier concentration) increases, the wave functions of the weakly bound localized carriers overlap. This forms an impurity band, and the material becomes metallic. Generalized phase diagrams for such a system have been proposed (Janisch, Gopal and Spaldin, 2005; Coey, Venkatesan and Fitzgerald, 2005a). Figure 8, from Coey, Venkatesan and Fitzgerald (2005a), shows an oxide system in which the magnetic state changes as a function of both TM dopant concentration and defect concentration. The shaded regions in the figure denote regions in which the carrier concentration is low, and the system is insulating. Clearly, as observed in experimental systems, ferromagnetism is predicted in both conducting and insulating films. In this model, the degree of magnetic coupling is strongly dependent on the defect (polaron) density, and thus the growth conditions. This argument could be used to explain the wide variation in moments reported by different groups for materials produced by different methods or in different conditions. This could also explain why poorer-quality, defect-rich films have been observed to exhibit stronger moments than high-quality films (Kaspar *et al*., 2005; Hong *et al*., 2005a).

When the dopant concentration, x, increases sufficiently to form pairs of dopant ions on neighboring sites, superexchange interactions will occur. The superexchange interaction is expected, in general, to be antiferromagnetic, so these pairs will yield a net reduction in the observed moment. Once the dopant concentration exceeds the percolation threshold, x_p, nearest-neighbor pairs will form throughout the material and it will become antiferromagnetic. The experimentally observed trend toward reduced moment with increased dopant agrees with the prediction of the formation of antiferromagnetically coupled pairs of magnetic dopant ions at high dopant concentrations.

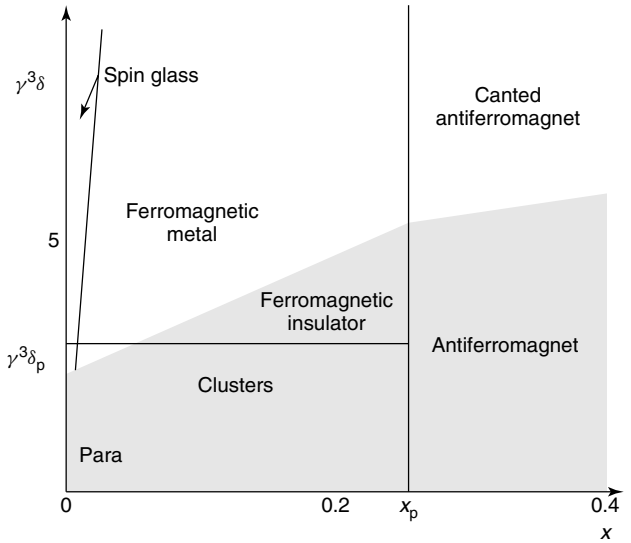

Figure 8. Proposed phase diagram for TM-doped oxides. The shaded region indicates insulating material. (Reproduced from Coey *et al*., 2005, with permission from Nature Publishing Group. © 2005.)

The Curie temperatures calculated for this model using typical material parameters are much lower than those actually observed, suggesting the need for extension of the model. Potentially, reasonable values for T_C could be obtained by hybridization of the donor impurity band orbitals with empty 3d bands from the magnetic impurities. Such hybridization would be most likely to occur near the beginning and the end of the 3d series of TM dopants where empty 3d bands cross the Fermi level. In support of this, experiments on a series of ZnO samples doped with small amounts of TM elements have shown that the magnetization of the resultant material varies across the TM series with peaks near the beginning and end of the series where hybridization is most likely to occur (Coey *et al*., 2005c).

Further supporting evidence is needed to confirm the impurity band model. In particular, it would be necessary to be able to quantify the defect concentration in a specimen in order to allow it to be compared with films grown by others or within the same group. Then the samples could be arranged by defect and dopant concentration to determine whether the phase diagram is reproduced. Another potential method for confirming the proposed phase diagram would be to vary the defect concentration within a specimen with a given dopant concentration to allow the effect of defect concentration on the magnetic and electrical properties to be reproducibly measured.

Finally we mention briefly the work on nitride materials. Magnetic doping of nitrides has paralleled the research on oxides, although to a large extent the research has concentrated primarily on Mn as the magnetic dopant. It is possible that magnetism in these materials may be described using similar models. Reviews of work on nitrides can be found in Pearton *et al*. (2003a,b). There have been two recent experimental reports of giant magnetic moments ($400-4000\,\mu_B$) in insulating material (Dhar *et al*., 2005a,b), GaN:Gd epilayers, and a theoretical description for conducting samples (Dalpian and Wei, 2005). Verification of these observations and the existing band structure calculations are necessary to provide impetus to further consider polarization effects in this system.

7.1 New developments

In this context, we note that a very recent analysis of magnetotransport effects in (Cd,Mn)Te quantum wells indicates that

a magnetic field induced increase in magnetic cluster size leads to large negative magnetoresistive effects (Jaroszynski *et al*., 2006) near but on the metallic side of the metal insulator transition. The change in carrier concentration in one and the same sample is achieved by gating of the device. The authors note the resemblance of these effects to mixed valence perovskites. Although the negative magnetoresistance is absent at higher temperatures, our view is that the effects in both systems are in the spirit of magnetic polarons described earlier in this text (von Molnár and Methfessel, 1967) and theoretically by Gor'kov and Kresin (1998, 2004). The authors point out, correctly, that in the present 2D modulation-doped system, the coulomb binding term is weak and thus the stability of the polarization cloud is not describable in the spirit of a strongly bound magnetic polaron. In fact, an observed concentration-independent conductivity requires that the polarization cloud maintain a constant radius regardless of carrier concentration. This is in striking contrast to, for example, Penney, Holtzberg, Tao and von Molnár (1974) and requires a modified model for the stability of the ferromagnetic conducting local polarization, that is, the magnetic polaron. Some of the physics associated with the formation of these magnetic polarons may have their origin in newly published data in the cobaltites. While $La_{1-x}Sr_xCoO_3$ can be described by classic magnetic polarons in the dilute limit (Giblin *et al*., 2005), in the more concentrated regions, the physical properties are more like those of conducting clusters in a dielectric matrix (Wu *et al*., 2005). This is similar to the mode of formation suggested by the results mentioned earlier on modulation-doped II–VI diluted heterostructures (Jaroszynski *et al*., 2006). Wu *et al*. prove conclusively, utilizing SANS, that $La_{1-x}Sr_xCoO_3$ phase separates into ferromagnetic metallic clusters having limited size distribution embedded in an insulating nonferromagnetic matrix. This, the authors argue persuasively, is a result of spontaneous magnetoelectronic, not chemical, phase separation. There is, furthermore, no direct spectroscopic evidence of the latter (Wu *et al*., 2005). Other indirect experimental evidence, such as a hopping transport signature with $\ln \rho \sim T^{-1/2}$ (Kennedy *et al*., 2004) as well as an intergranular giant magnetoresistance, however, are characteristic of chemically multiphase materials as well. It is apparent that these novel experimental results will require further theoretical understanding of magnetic polarons.

8 CONCLUSION

In summary, we have shown, utilizing specific experimental evidence drawn principally from transport, optics, and scattering experiments that magnetic polaron descriptions can explain many of the observed properties of magnetic semiconductor systems, both dilute and concentrated. They also show promise of being able to describe the properties of systems of recent interest such as the dilute magnetic oxides. Extensions of these concepts to the cobaltites and modulation-doped II–VI diluted two dimensional electron systems (2DES) will require improved understanding of polaron stability.

NOTES

[1] This chapter represents an expansion on and an update of a review published earlier. von Molnár, S., Terry, I. and Penney, T. (1995) in *Polarons and Bipolarons in High-T_C Superconductors and Related Materials* (Eds, Salje, E. K. H., Alexandrov, A. S. and Liang, W. Y.) Press Syndicate of the University of Cambridge, Cambridge, pp. 437.

ACKNOWLEDGMENTS

The authors first and foremost thank Mrs Linda Lynes who spent many hours assuring accuracy of references and the general format of the manuscript. They are also grateful to Drs C. Leighton, V. Dobrosavljevic, and R.J. Kennedy for several enlightening discussions which we hope improved this brief review.

1 INTRODUCTION

At low temperatures, a small concentration of magnetic impurities – atoms or ions with a nonzero magnetic moment – can dramatically affect the behavior of conduction electrons in an otherwise pure metal. This phenomenon, known as the *Kondo effect* (Kondo, 1964), has been a leitmotif of solid-state physics since the 1960s. Nearly a decade ago, the Kondo effect was discovered in a new system (Goldhaber-Gordon *et al*., 1998a), in which the local magnetic moment belongs not to an atom but to a lithographically defined droplet of electrons known as a *quantum dot* or *artificial atom* (Kastner, 1993). When the droplet contains an odd number of electrons, it has a net spin and hence may be thought of as a magnetic artificial atom. Nearby metal or semiconducting electrical leads play the role of the host metal.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

The artificial atom system offers several important advantages for the study of the Kondo effect:

1. A single site is measured, rather than a statistical average over many sites.
2. The microscopic states of the system are better defined and easier to tailor than in bulk systems.
3. Most of the important parameters can be precisely measured and tuned *in situ*.
4. The local site can be studied out of equilibrium and in regimes that are inaccessible in other contexts.

In this chapter of the handbook, we review how researchers around the world have applied these advantages to create a renaissance in the study of the Kondo effect. Though this approach was initially inspired by theory (Glazman and Raikh, 1988; Ng and Lee, 1988) and continues to be strongly informed by it, we organize our review around experimental developments in mesoscopic systems.

1.1 Background of the Kondo effect: dilute magnetic alloys

At relatively high temperatures, the resistivity of a metal is dominated by electron–phonon scattering. As the temperature is lowered well below the Debye temperature, the scattering rate, and hence the phonon contribution to resistivity, decreases as T^5. At sufficiently low temperatures, phonon-induced scattering becomes insignificant and resistivity saturates at a finite value determined by scattering from defects in the crystal lattice. In the 1930s, researchers noticed that this simple picture did not always hold. Measurements of Au cooled below 10 K sometimes showed a resistivity

rise rather than saturation as the temperature was lowered further (de Haas, de Boer and van den Berg, 1934). The effect remained an enigma until the 1960s when experimental evidence correlated the low-temperature resistivity rise with the presence of dilute magnetic impurities in the metal (Sarachik, Corenzwit and Longinotti, 1964). Inspired by the strong evidence that individual magnetic impurities were responsible for the resistivity rise, Kondo considered a model involving an antiferromagnetic interaction between the local moment and the sea of conduction electrons (Kondo, 1964). Using perturbation theory, Kondo found that the antiferromagnetic interaction leads to a logarithmic rise in electron-impurity scattering with decreasing temperature.

Though Kondo's work was a crucial breakthrough, calculations using this theoretical framework inherently produced unphysical logarithmic divergences. Finding a solution to this conundrum became known as the *Kondo Problem*. The problem was finally solved by Wilson (1975), who developed a new renormalization group (RG) technique for the purpose. Wilson's RG calculations showed that at temperatures below a characteristic Kondo temperature T_K, a magnetic impurity would form a singlet with the surrounding sea of conduction electrons. Despite this success in determining the ground state (and thermodynamic properties) of a magnetic impurity in a metal, nearly two decades would pass before the development of numerical renormalization group (NRG) techniques that could accurately calculate transport properties such as resistivity over a broad range of temperatures (Costi, Hewson and Zlatic, 1994).

1.2 Tunneling: Kondo in a new geometry

Since the Kondo effect is a property of magnetic impurities in a host metal, it should also be observable in transport through magnetic impurities sandwiched between two metal leads (Appelbaum, 1966). This was borne out in both large tunnel junctions with many impurities (Wyatt, 1964) and more recently in a nanometer-scale junction containing a single impurity (Gregory, 1992; Ralph and Buhrman, 1994). In this geometry, the Kondo effect enhances conductance rather than resistivity at low temperature and low bias voltage (Appelbaum, 1966).

The advent of high-mobility GaAs heterostructures in the 1980s ushered in the modern era of mesoscopic semiconductor physics: the study of electronic phenomena at intermediate spatial scales, between atomic and macroscopic. Through concurrent advancement in lithographic technology, the first artificial atoms were created in patterned GaAs heterostructures in the late 1980s (Reed *et al*., 1988; van Wees *et al*., 1989; Meirav, Kastner and Wind, 1990). Around the same time, two theoretical teams pointed out that this type of system can behave like a magnetic impurity and hence should exhibit the Kondo effect (Glazman and Raikh, 1988; Ng and Lee, 1988). Indeed, ten years later the Kondo effect was observed in lithographically defined quantum dots (Goldhaber-Gordon *et al*., 1998a; Cronenwett, Oosterkamp and Kouwenhoven, 1998; Simmel *et al*., 1999). Due to the unprecedented degree of flexibility and control available in artificial atom systems, a wave of experimental work followed, exploring a variety of Kondo regimes untouched by previous efforts.

Several other new and interesting Kondo systems have emerged in recent years, as well. The Kondo effect has also been observed in scanning tunneling microscopy (STM) measurements of individual surface adatoms (Madhavan *et al*., 1998; Li, Schneider, Berndt and Delley, 1998) and metal complexes (Zhao *et al*., 2005), allowing, for example, the study of the spatial characteristics of Kondo interactions (Madhavan *et al*., 1998; Manoharan, Lutz and Eigler, 2000). Electrons localized on a single molecule or a single carbon nanotube can exhibit Kondo effects stemming from local degeneracies not easily achieved in a GaAs artificial atom (Park *et al*., 2002; Liang *et al*., 2002), and can be coupled to reservoirs with exotic properties (superconducting, ferromagnetic). Though a wide range of Kondo systems have played important roles in developing our understanding of the Kondo effect, this review will focus mainly on the diverse set of experiments performed using mesoscopic quantum dot systems.

2 EXPERIMENTAL SIGNATURES OF THE SPIN-1/2 KONDO EFFECT

In this section, we review the characteristic signatures of the Kondo effect in the context of a spin-1/2 quantum dot coupled to two reservoirs. Consideration of more complex scenarios is left to later sections.

2.1 Quantum dots

Our discussion of experimental results draws primarily on work performed on three types of quantum dots, each offering a different set of advantages: lateral and vertical semiconductor dots, and carbon nanotube quantum dots (Figure 1). Lateral quantum dots are formed by depleting a subsurface two-dimensional electron gas (2DEG) using lithographically defined metallic gates, as shown in Figure 1(a). The 2DEG resides at the interface of a semiconductor heterostructure (e.g., GaAs/AlGaAs), located tens to hundreds of nanometers below the surface. The quantum dot consists of a pool of confined electrons, tunnel coupled to extended sections of the

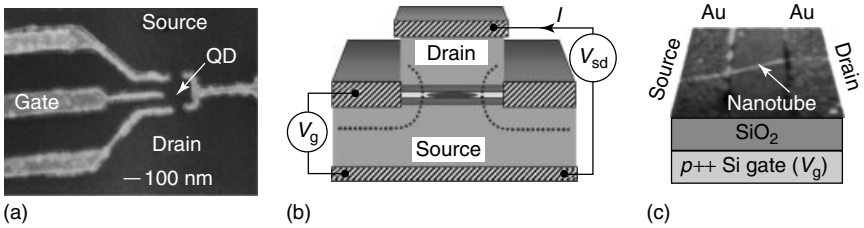

Figure 1. The Kondo effect has been seen in a variety of quantum dot geometries such as (a) lateral quantum dots (scanning electron microscopy (SEM) image). (b) Vertical quantum dots (schematic). (Reproduced from Jesper *et al*., 2000, with permission from Nature Publishing Group. © 2000.)

2DEG, which serve as leads. Several nearby gate electrodes electrostatically control the quantum dot electron occupancy, as well as the dot–lead couplings. In principle, the number of electrons can be reduced to zero; however, in many lateral quantum dot geometries, the conductance through the quantum dot's contacts is 'pinched off' by the increasingly negative gate voltage before the dot is entirely emptied.

The vertical quantum dot geometry, shown in Figure 1(b), allows the formation of a small, well-coupled, few-electron quantum dot whose conductance remains measurable all the way down to the expulsion of the last electron. This allows accurate determination of the electron occupancy, as discussed later in this section. Another important difference between lateral and vertical quantum dots is the number of tunneling modes, or channels, that couple the dot to the leads [1]. Typically, the dot–lead contacts in lateral dots are single-mode quantum point contacts (QPCs), while the wide lead–dot contact area in vertical dots contains several partially transmitting modes.

A carbon nanotube quantum dot is created using a single carbon nanotube deposited on a conducting substrate covered by a thin insulator (e.g., SiO_2/n^{++}-Si). Lithographically defined metal leads contact the nanotube, and the conducting substrate is biased to modify the electron occupancy of the nanotube (Figure 1c). While the nanotube–lead couplings cannot be finely controlled, this geometry allows for the creation of a wide variety of leads, such as superconducting and magnetic, which are difficult, if not impossible, to achieve in semiconductor heterostructures. For a further discussion of quantum dots, including the Kondo effect, we encourage readers to examine several recent reviews (Kouwenhoven *et al*., 1997; Kouwenhoven, Austing and Tarucha, 2001; Yoffe, 2001; Pustilnik and Glazman, 2004; Giuliano, Naddeo and Tagliacozzo, 2004).

2.2 Theoretical background

Here, we present only a brief theoretical description of the Kondo effect. The reader may consult several references for a more complete theoretical description (Gruner and Zawadowski, 1974; Wilson, 1975; Nozières and Blandin, 1980; Andrei, Furuya and Lowenstein, 1983; Hewson, 1993; Costi, Hewson and Zlatic, 1994; Pustilnik and Glazman, 2004 (See also **The Kondo Effect, Volume 1**).

2.2.1 Kondo Hamiltonian

The Kondo effect arises when a degenerate local state is coupled to a reservoir of mobile electrons. The system is well described by the Anderson Hamiltonian

$$H = \sum_{k,\sigma} \varepsilon_k c^\dagger_{k\sigma} c_{k\sigma} + \sum_{\sigma} \varepsilon_0 d^\dagger_\sigma d_\sigma + U d^\dagger_\uparrow d_\uparrow d^\dagger_\downarrow d_\downarrow + \sum_{k,\sigma} \left(v_k d^\dagger_\sigma c_{k\sigma} + v^*_k \, c^\dagger_{k\sigma} d_\sigma \right) \quad (1)$$

which was originally proposed to describe a magnetic impurity atom in a metal (Anderson, 1961). The first term represents the kinetic energy of electrons in the reservoir, labeled by their momentum (k) and spin (σ). The second term is the quantized energy of localized electrons in a single spin-degenerate state near E_F – all other quantum dot levels are assumed to be either completely full (well below E_F) or completely empty (well above E_F), and hence can be safely ignored. The third term accounts for interactions among localized electrons: a second electron added to the local site costs more than the first electron, by an amount denoted as the *charging energy* U. This is crucial, since it allows for the possibility that the doubly degenerate site can be occupied by just a single electron. In this case, the site acts as a magnetic impurity and can exhibit the Kondo effect. The final term describes spin-conserving tunneling on and off the local site, with strength v_k. A schematic of the Anderson model is shown in Figure 2. A spin-degenerate quantum dot is probably the most exact experimental realization of the Anderson model.

With a few simple assumptions, which are generally well justified for a quantum dot with odd occupancy,

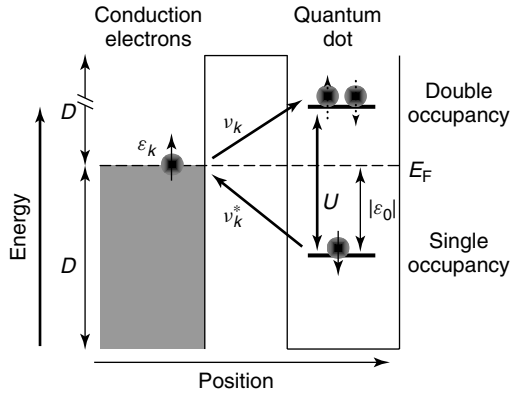

Figure 2. Schematic diagram of the Anderson model as applied to a singly occupied spin-degenerate quantum dot state coupled to an electron reservoir. The parameters are discussed in the text.

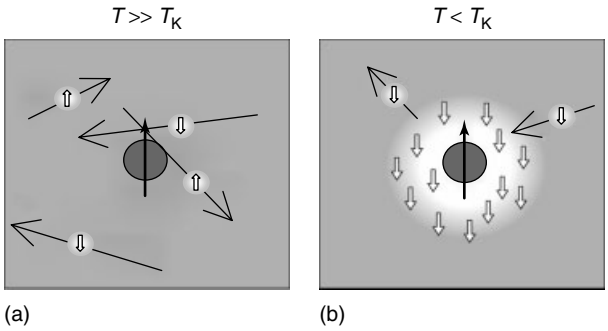

Figure 3. A magnetic impurity in a sea of conduction electrons. (a) Above the Kondo temperature (T_K), the conduction electrons are only weakly scattered by the magnetic impurity. (b) Below T_K, the conduction electrons screen the local spin to form a spin singlet. The formation of the Kondo screening cloud enhances the effective scattering cross section of the magnetic impurity.

the interaction between the conduction electrons and the quantum dot (final term in equation (1)) can be approximated as an antiferromagnetic coupling,

$$H_{\text{int}} = J s_{\text{cond}} \cdot S_{\text{QD}} \tag{2}$$

Equation 2 is known as the s–d or the *Kondo Hamiltonian* (Kondo, 1964; Schrieffer and Wolff, 1966; Kasuya, 1956; Yosida, 1957), as alluded to previously. S_{QD} is the net spin of the quantum dot, while s_{cond} is the sum of spin operators for the conduction electrons (cf. Pustilnik and Glazman, 2004). The strength of the antiferromagnetic coupling depends on the microscopic parameters of the Anderson model, according to

$$J \sim |v|^2 \left(\frac{1}{-\varepsilon_0} + \frac{1}{\varepsilon_0 + U} \right) \tag{3}$$

Here, ε_0 is measured relative to E_F and the interaction strength is taken to be a constant ($v_k = v$) over a finite bandwidth (D) and zero otherwise, as indicated in Figure 2.

2.2.2 *Kondo ground state*

The ground state of the Kondo Hamiltonian is not twofold degenerate, but is instead a spin singlet in which the spin of a localized electron is matched with the spin of delocalized electrons to yield a net spin of zero. This 'Kondo screening cloud' is shown schematically in Figure 3. Due to phase space constraints, the Kondo interaction predominantly affects electrons near the Fermi surface. This mixing of conduction and local electron states leads to the characteristic signature of the formation of the Kondo singlet: the appearance of a narrow resonance at the Fermi energy with width proportional to the strength of the Kondo interaction [2].

Owing to its nonconventional nature, the Kondo singlet's 'binding energy' is not simply proportional to J. Typically expressed as a Kondo temperature (T_K), the binding energy can be calculated perturbatively using equation (2) to give

$$T_K \sim D\sqrt{\rho J}\exp(-1/2\rho J) \tag{4}$$

where ρ is the density of states in the reservoir at energy E_F (Hewson, 1993). The formation of the Kondo singlet is a continuous phase transition, and T_K should be interpreted as the cross-over energy scale for this transition. It is important to realize that T_K is not a well-defined energy scale: equally valid definitions can differ by a constant multiplicative factor. In this review, we use a definition suggested by Costi, Hewson, and Zlatic (1994) and introduced for quantum dots by Goldhaber-Gordon *et al*. (1998b): T_K is the temperature at which the Kondo conductance has risen to half its extrapolated zero-temperature value (see Section 2.3.3).

The expression for T_K can be rewritten in terms of quantities that are more easily controlled and measured in quantum dot experiments (Haldane, 1978):

$$T_K \sim \sqrt{\Gamma U}\exp(\pi\varepsilon_0(\varepsilon_0 + U)/\Gamma U) \tag{5}$$

Here, Γ is the rate for electron on and off the dot. The spin-1/2 Kondo effect occurs only when the local site is singly occupied ($\varepsilon_0 < 0$ and $\varepsilon_0 + U > 0$), so the exponent in equation (5) is negative, as expected from equation (4). These equations break down near the charge degeneracy points ($\varepsilon_0 = 0$ and $\varepsilon_0 + U = 0$), where charge fluctuations produce mixed valence rather than Kondo behavior (Costi, Hewson and Zlatic, 1994). Coupling additional leads to the quantum dot modifies Γ, but does not affect the overall Kondo behavior. The leads behave as a single collective reservoir, as long as Kondo processes can freely exchange

electrons between each pair of reservoirs (Glazman and Raikh, 1988).

T_K is maximized when the quantum dot state is energetically close to E_F ($\varepsilon_0 \sim 0$) and strongly coupled to the leads (large Γ). Finite charging energy (U) and level spacing (Δ) put a limit on T_K in quantum dots, since electrons are no longer localized on the dot for $\Gamma > \min(U, \Delta)$. U and Δ increase with decreasing device size, yielding a maximal T_K in the range of 0.1–1 K for typical semiconductor quantum dots and up to 10 K in carbon nanotube–based devices. For comparison, T_K in excess of 500 K has been observed for atomic impurities in bulk systems (Gruner and Zawadowski, 1974).

The formal spatial scale of the Kondo cloud is given by

$$\xi_K \sim \hbar v_F / k_B T_K \tag{6}$$

where v_F is the Fermi velocity (Sorensen and Affleck, 1996). $\xi_K \sim 1\,\mu m$ for typical semiconductor quantum dots in the Kondo regime, which gives an estimate of the spatial extent of Kondo correlations. The spatial properties of the Kondo cloud have proved difficult to measure for several reasons. The Kondo screening cloud mainly involves spin rearrangement. However, local spin density is dynamic, since the spin on the local site is rapidly changing, and the exponential decay is modulated further by polynomial decay factors (Barzykin and Affleck, 1996). In addition, charge rearrangement due to Kondo singlet formation is minimal and occurs only at length scales on the order of λ_F. Local probes, such as STM, generally measure the total density of states, which is modified on similar short spatial scales (Madhavan *et al*., 1998; Újsághy, Kroha, Szunyogh and Zawadowski, 2000). This is understood to stem from oscillations and polynomial decay that modulate the slow exponential decay of spin polarization in the electron gas at distances greater than λ_F from the local moment (Barzykin and Affleck, 1996).

2.3 Kondo transport in quantum dots

The formation of the Kondo screening cloud enhances the scattering of conduction electrons by the local magnetic site. Hence, the resistivity of a bulk metal with a small concentration of magnetic impurities rises as temperature is decreased below the characteristic Kondo temperature for that impurity/metal system. In a geometry where transport is dominated by tunneling through a magnetic site, the enhanced scattering has the opposite effect: *conductance* rises for $T < T_K$, as a new mechanism for transport becomes available (Appelbaum, 1966; Ng and Lee, 1988; Costi, Hewson and Zlatic, 1994). In transport through semiconductor quantum dots, the Kondo effect emerges whenever the dot contains an unpaired spin, as is the case when an odd number of electrons occupy the dot. As the occupancy of a dot is tuned by a nearby gate, the low-temperature conductance alternates between high (odd occupancy) and low (even occupancy), as seen in Figure 4(a). The high conductance for odd occupancy disappears as the coupling to the leads (Γ) is reduced (Figure 4b): T_K becomes lower than the base temperature of the measurement apparatus (cf. equation (5)). In this 'Coulomb blockade' (CB) regime, conduction occurs only near the charge degeneracy points.

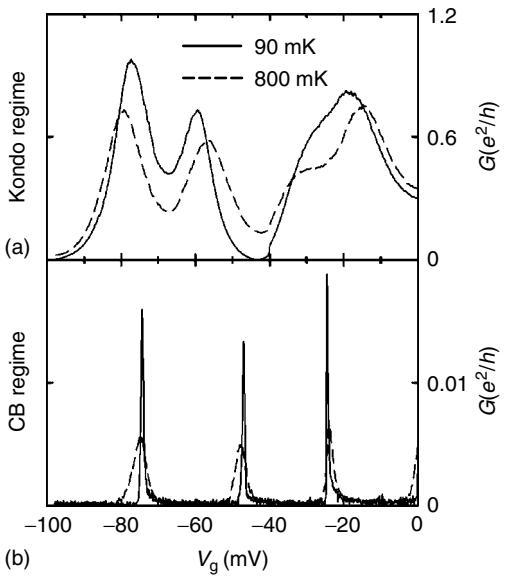

Figure 4. Linear conductance through the lateral quantum dot shown in Figure 1(a), as a function of gate voltage. From left to right, the quantum dot electron occupancy increases by four and three in (a) and (b) respectively. (a) Kondo regime: For strong lead–dot coupling, the Kondo effect enhances conductance for odd occupancy at 90 mK. At higher temperatures (800 mK), the Kondo effect is partially suppressed and transport proceeds through temperature-broadened single-particle levels. (b) Coulomb blockade (CB) regime: For weak dot–lead coupling ($\Gamma \ll U, \Delta$), the Kondo temperature is lower than the base temperature of the experiment (90 mK) and transport occurs only at the charge degeneracy points. Note: the peaks in (b) have been shifted by +120 mV and do not correspond to the same electronic states as in (a). (Reproduced from D. Goldhaber-Gordon *et al*., 1998, with permission from the American Physical Society. © 1998.)

The Kondo-mediated transport through a quantum dot may be distinguished from other mechanisms for conductance enhancement by the following distinctive features:

1. Even–odd alternation of conductance as a function of dot occupancy (the Kondo effect occurs only for odd occupancy).
2. Enhanced conductance at low temperature, with a characteristic temperature dependence.
3. Enhanced conductance at zero bias relative to finite bias.

4. Suppression of conductance by magnetic field, which splits the local spin degeneracy.
5. Recovery of enhanced conductance at finite magnetic field by application of a bias voltage equal to the Zeeman splitting.

The above list is useful for demonstrating the occurrence of a Kondo effect, but is not an exhaustive or quantitative description of spin-1/2 Kondo. Note that some of the listed features can only be observed in systems where the local site occupancy can be tuned (i.e., 1) or where a finite bias can be applied across the local site(s) (i.e., 3 and 5).

2.3.1 *Even–odd effect*

The low-temperature Kondo conductance enhancement is expected to occur whenever a local state is degenerate and partially filled. In the absence of additional degeneracies, this occurs whenever the number of electrons on the dot is odd. Though early Kondo dot measurements exhibited conductance enhancements in alternating CB valleys, the researchers could not directly demonstrate that the enhancement occurred for odd rather than even occupancies, since the initial occupancy of the dot was unknown (Goldhaber-Gordon *et al*., 1998a). Indeed, in later sections, we discuss a variety of Kondo effects that do not require a spin-1/2 dot state and hence do not follow the even–odd rule. More recent quantum dot devices use either of two methods to conclusively determine the total electron occupancy. In one method, the electron number is determined by counting CB peaks as the quantum dot is emptied by an increasingly negative gate voltage. This technique works best in vertical quantum dots (Tarucha *et al*., 1996) (Figure 1b), as well as certain lateral dots (Ciorga *et al*., 2000), which remain conducting as the occupancy is reduced and counted down to zero. A second technique uses a QPC fabricated close to the quantum dot, to serve as a detector of the dot's occupancy (Sprinzak *et al*., 2002). Each electron added to the quantum dot electrostatically alters the conductance of the QPC. This method works even if transport through the quantum dot is so slow as to be immeasurable with conventional methods (fewer than around 1000 electrons per second). These methods confirm that in small GaAs quantum dots spin-1/2 Kondo and even–odd conductance alternation are the rule rather than the exception.

2.3.2 *Dependence on external parameters*

Kondo conductance through a quantum dot has a characteristic and calculable dependence on external parameters such as temperature, magnetic field, and voltage across the dot (Pustilnik and Glazman, 2004). We can consider two regimes: low energy and high energy, distinguished by whether the perturbations $k_B T$, eV, and $g\mu_B B$ are small or large compared to $k_B T_K$. At low energy, a Kondo impurity acts as an elastic scatterer, and nearby conduction electrons behave as in a conventional Fermi liquid, albeit with slightly modified numerical parameters (Nozières, 1974). Hence, for $k_B T$, eV, and $g\mu_B B \ll k_B T_K$ the Kondo spectral function and the associated transport through a spin-1/2 Kondo dot display quadratic dependence on external parameters, reflecting the E^2 scattering rate of quasiparticles in a Fermi liquid,

$$G(X) \sim G_0(1 - C(X/k_B T_K))^2$$
$$X = k_B T, eV, g\mu_B B \ll k_B T_K \quad (7)$$

$G_0 = G(X = 0)$, and the constant C is slightly different for the three perturbations.

In the opposite extreme, $k_B T$, eV, or $g\mu_B B \gg k_B T_K$, Kondo transport is well described by a perturbative treatment of the excitation and shows a logarithmic dependence on energy,

$$G(X) \sim 1/ln^2(X/k_B T_K)$$
$$X = k_B T, eV, g\mu_B B \gg k_B T_K \quad (8)$$

The two regimes evolve smoothly and monotonically into one another with no sharp features appearing at T_K. No analytic expression linking the two regimes has been derived, though an empirical expression for $G(T)$ that matches NRG calculations (Costi, Hewson and Zlatic, 1994) over the entire temperature range has been widely adopted by experimentalists (Goldhaber-Gordon *et al*., 1998b). We note that even though the three perturbations have similar effects on conductance, the mechanism is slightly different in each case, as discussed in the next two sections. The evolution of shot noise is predicted to follow forms similar to equations (7) and (8) (Meir and Golub, 2002), but with an effective fractional charge of $5/3e$, reflecting the presence of both elastic and inelastic scattering even at low temperatures (Sela, Oreg, von Oppen and Koch, 2006).

2.3.3 *Temperature dependence*

The conductance behavior predicted by equations (7) and (8) can be seen in temperature-dependent conductance measurements of a Kondo dot, as shown in Figure 5. As temperature is raised, the conductance in the odd valleys decreases because of suppression of the Kondo effect. In contrast, conductance in the even valleys increases because of thermal broadening of the bare quantum dot levels (Pustilnik and Glazman, 2004). The scaled temperature-dependent conductance for several gate voltage values in the Kondo valley is shown in Figure 5(b). The Kondo conductance shows

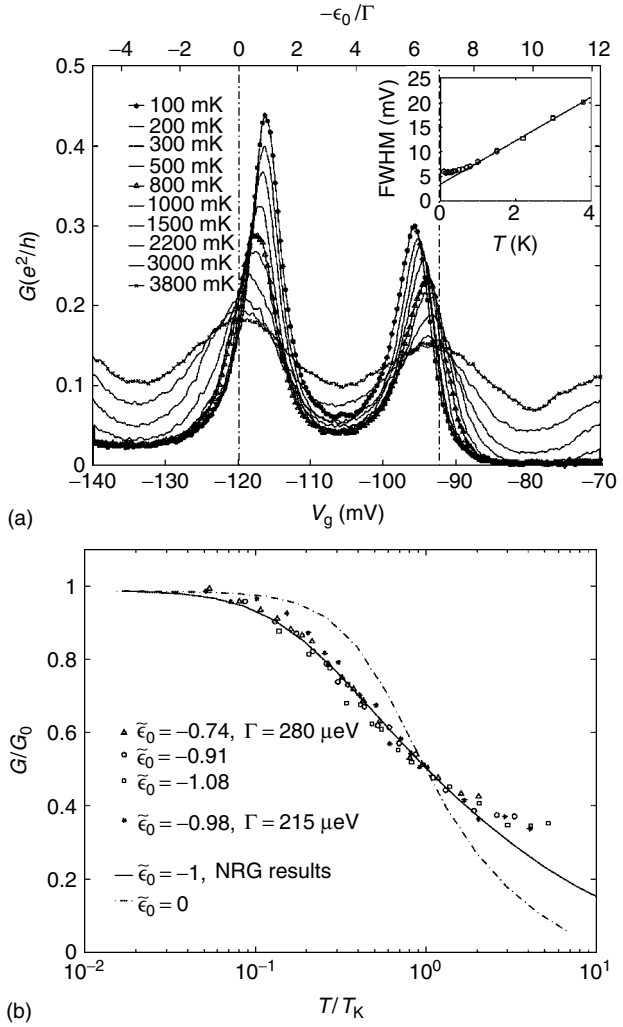

Figure 5. (a) Temperature dependence of the conductance in the Kondo valley. The vertical dashed lines indicate the location of the charge degeneracy points (i.e., $\varepsilon_0 = 0$ or $\varepsilon_0 + U = 0$), as deduced from data for $T \gg T_K$. Inset: The extrapolated linear temperature dependence of the Coulomb blockade peak width at $T = 0$ gives $\Gamma = 295 \pm 20\,\mu$eV. The slope of the line determines the conversion factor between the applied gate voltage (V_g) and ε_0. (b) Normalized conductance (G/G_0) as a function of normalized temperature (T/T_K) for several points along the Kondo valley. Here $\sim\varepsilon = \varepsilon_0/\Gamma$. G_0 and T_K were extracted by fitting the temperature dependence to equation (9). The data shown here are from the lateral quantum dot device shown in Figure 1(a). (Reproduced from D. Goldhaber-Gordon *et al.*, 1998, with permission from the American Physical Society. © 1998.)

the characteristic T^2 saturation at low temperatures, crossing over to a logarithmic temperature dependence as T approaches T_K. The empirically derived formula alluded to above,

$$G(T) = G_0(T_K'^2/(T^2 + T_K'^2))^s \qquad (9)$$

provides a remarkably good fit over the whole temperature range (Goldhaber-Gordon *et al.*, 1998b). The constant s determines the slope of the conductance falloff. Using a value $s = 0.22$ matches the slope found in NRG calculations for spin-1/2 Kondo systems (Costi, Hewson and Zlatic, 1994). Here, $T_K' = T_K/(2^{1/s} - 1)^{1/2}$, which is equivalent to defining T_K such that $G(T_K) = G_0/2$, as noted earlier. The extracted values of T_K and G_0 across the Kondo valley are shown in Figure 6. As predicted by equation (5), T_K is maximal when the quantum level resides close to E_F.

At temperatures above T_K, non-Kondo conductance channels can develop (Pustilnik and Glazman, 2004), and this

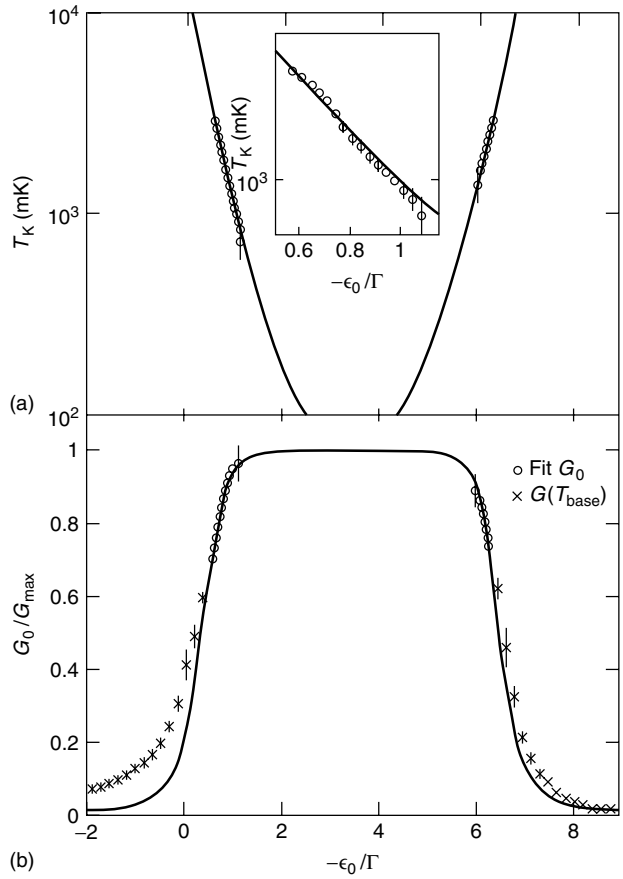

Figure 6. (a) Values of T_K across the Kondo valley shown in Figure 5, extracted by fitting the temperature-dependent conductance to the Kondo form (equation (9)). The behavior is well described by equation (5) (solid line). Inset: Expanded view of the left side of the figure, showing the quality of the fit. (b) Values of G_0 across the Kondo valley extracted from the temperature fits in part (a) (open circles) or from base temperature conductance (crosses). The solid line shows $G_0(\varepsilon_0)$ predicted by Wingreen and Meir (1994). $G_{max} = 0.49e^2/h$ and $0.37e^2/h$ for the left and right peak, respectively. (Reproduced from D. Goldhaber-Gordon *et al.*, 1998, with permission from the American Physical Society. © 1998.)

leads to deviations from equation (9). Occasionally a better fit to $G(T)$ can be achieved by adding a temperature-independent offset to the Kondo form (equation (9)). Though convenient, using such an offset in analyzing Kondo behavior is not yet well-established as physically valid.

2.3.4 *Dependence on bias and magnetic field*

The E^2 dependence of the Kondo spectral function can be probed by applying a bias across the dot (Goldhaber-Gordon *et al*., 1998a; Cronenwett, Oosterkamp and Kouwenhoven, 1998). The spectrum shows a narrow zero-bias anomaly, referred to as the *Kondo resonance*, that is present across the whole odd-occupancy Coulomb valley (Figure 7). For small biases, the Kondo conductance peak falls off with V^2. The Kondo peak broadens with increasing temperature, and the extrapolated zero-temperature half width at half maximum is approximately $2T_K$ (Costi, 2000). Exact interpretation of the Kondo peak shape is complicated by nonequilibrium processes (Wingreen and Meir, 1994; Schiller and Hershfield, 1995), which are discussed further in Section 3.2.

An applied magnetic field lifts the degeneracy between the two spin states on the quantum dot. The asymmetry between the two spin states acts to suppress Kondo correlations in much the same way as the asymmetry created by an applied bias. Progressively higher magnetic fields split the Kondo spectral function, which can be probed by the measurement of differential conductance as a function of bias (Goldhaber-Gordon *et al*., 1998a; Cronenwett, Oosterkamp and Kouwenhoven, 1998). These measurements are discussed in Section 3.2.

2.3.5 *Universal scaling*

The similarity of the effects of temperature, bias, and magnetic field on the Kondo effect is neatly encompassed by a series of theoretically predicted universal scaling relations. In the context of Kondo transport, the behavior of different Kondo systems can be collapsed onto a single curve once each curve is scaled appropriately using only the Kondo temperature and the zero-temperature conductance, T_K and G_0, respectively (Ralph, Ludwig, von Delft and Buhrman, 1994; Schiller and Hershfield, 1995). The relation between temperature and bias can be expressed as

$$\frac{(G(V=0,T)-G(V,T))/G_0}{CT^{\alpha}} = F(eV/k_BT) \qquad (10)$$

Here, $F(eV/k_BT)$ is a universal function that depends on the type of Kondo effect, but not on the exact details of the Kondo system at hand. The scaling constants G_0 and C are defined by the low-temperature expansion for $G(T)$ (equation (7)). The exponent $\alpha = 2$ for a spin-1/2 quantum dot, but can take on different values in more exotic Kondo systems (Ralph, Ludwig, von Delft and Buhrman, 1994). Though the scaling properties of Kondo systems are frequently used in analyzing Kondo measurements (Figure 5b), few experimental measurements of universal Kondo scaling functions or the expected deviation from universality (Majumdar, Schiller and Hershfield, 1998) have been reported to date (Ralph, Ludwig, von Delft and Buhrman, 1994).

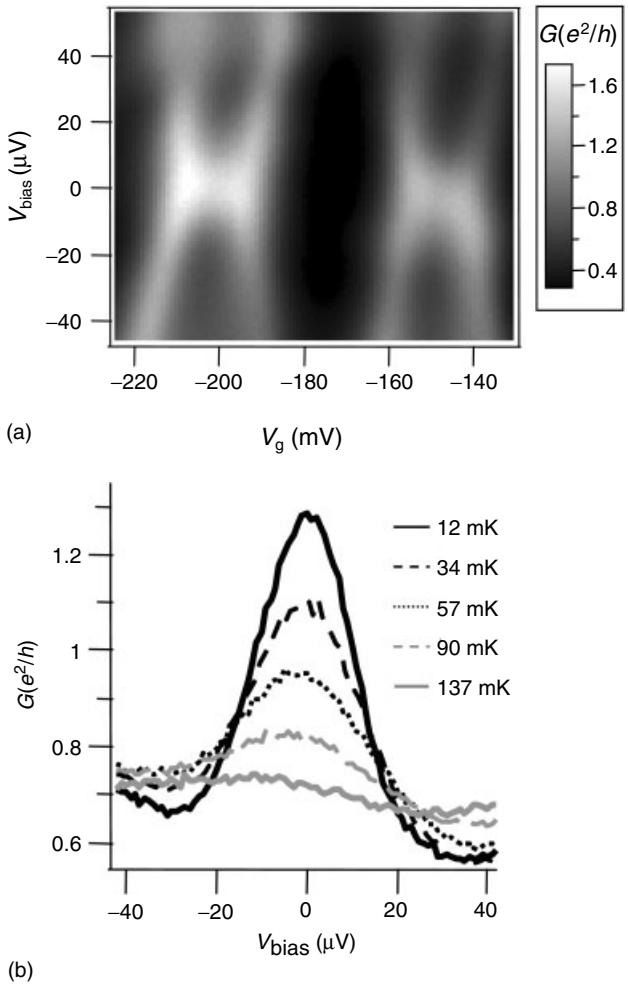

Figure 7. (a) Low-temperature ($T = 12$ mK) differential conductance (dI/dV) through a lateral quantum dot, as a function of gate voltage and applied bias in the Kondo regime. In the absence of the Kondo effect, dI/dV is nonzero only when a quantum dot energy level is aligned with the Fermi energy of one of the leads (cf. Kouwenhoven, Austing and Tarucha, 2001). The resulting 'Coulomb diamonds' are modified by the Kondo effect: a Kondo resonance appears at zero bias across the whole Coulomb valley for odd occupancy. The Kondo effect also alters finite bias conduction through the quantum dot levels. (b) Temperature dependence of the Kondo resonance in the middle of the Kondo valley ($V_g = -203.5$ mV).

2.4 Transmission phase shift and unitary limit

The zero-temperature Kondo conductance through a two-lead quantum dot can also be derived via the Landauer formalism and Friedel sum rule, giving

$$G_0 = \frac{2e^2}{h}\left[\frac{2\Gamma_1\Gamma_2}{\Gamma_1^2+\Gamma_2^2}\right]^2 \frac{1}{2}\sum_\sigma \sin^2(\delta_\sigma) \qquad (11)$$

where Γ_i is the rate of tunneling between the local site and the ith lead and δ_σ is the transmission phase shift of the σ spin channel (see Pustilnik and Glazman, 2004). For tunneling through a quantum dot in the CB regime, the transmission phase shift is changed by π each time one CB peak is tuned through the Fermi energy. Surprisingly, owing to the equivalence of the two spin states brought about by the Kondo effect, the transmission phase shift evolves instead by $\pi/2$ in the Kondo regime at $T = 0$ (Figure 8d) (Gerland, von Delft, Costi and Oreg, 2000). As the temperature is raised to $T \sim T_K$, the phase shift evolves to the more conventional π phase shift, as seen in Figure 8(b).

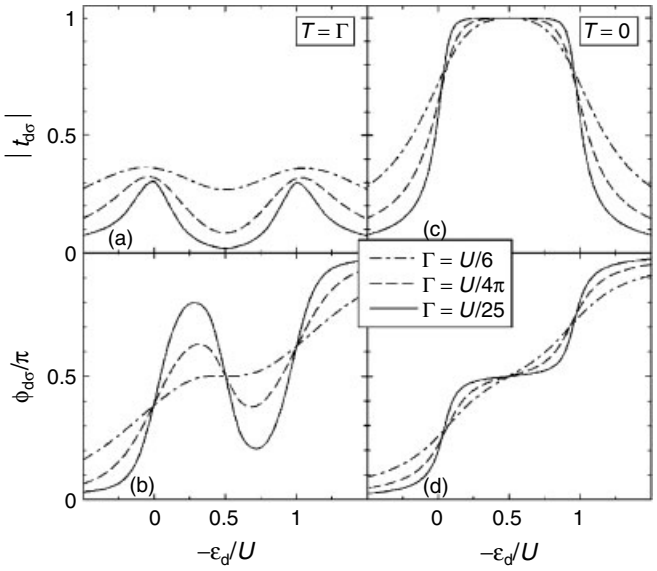

Figure 8. Theoretical temperature and coupling dependence of the transmission amplitude ($|_{d\sigma}|$) and phase ($\Phi_{d\sigma}$) for transport through a quantum dot, as a function of the normalized energy of the quantum dot level (ε_0/U). Each pane plots results for three values of dot–lead coupling (Γ). The transmission amplitude is normalized to $2e^2/h$. (a and b) The two panels on the left show calculations for $T = \Gamma > T_K$. In this regime, transport occurs mainly through thermally broadened quantum dot levels. (c and d) The two panels on the right show calculations for $T = 0$. The Kondo effect is in the unitary limit, giving a $2e^2/h$ conductance throughout the Kondo valley. In this regime, the phase shift is $\pi/2$ in the Kondo valley. (Reproduced from Ulrich Gerland *et al.*, 2000, with permission from the American Physical Society. © 2000.)

While the Kondo phase shift cannot be determined in bulk measurements, several mesoscopic measurements can determine it directly (Ji *et al.*, 2000; Sato *et al.*, 2005). One of the most successful approaches to measuring transmission phase shifts involves using an Aharonov–Bohm (AB) interferometer geometry like the one shown in Figure 9(a) (Yacoby, Heiblum, Mahalu and Shtrikman, 1995). Electrons can either tunnel through the quantum dot or travel ballistically through a reference arm. The relative phase of these two paths depends on the magnetic flux through the loop and the transmission phase shift acquired in tunneling through the quantum dot. The transmission phase shift is deduced by examining how the interference pattern changes as a function of the energy ε_0 of a localized state on the quantum dot. The Kondo phase shifts extracted from these experiments are somewhat larger than the theoretically predicted value, as seen in Figure 9(c) (Ji *et al.*, 2000; Ji, Heiblum and Shtrikman, 2002). Transmission phase shifts can be measured using other two-path interference geometries, such as a quantum wire side-coupled to a quantum dot (Sato *et al.*, 2005). In these devices, the measured phase shift is closer to the theoretically predicted value of $\pi/2$. More recent experiments (Avinun-Kalish *et al.*, 2005; Neder *et al.*, 2006) and theoretical work (Aharony, Entin-Wohlman and Imry, 2003; Aharony and Entin-Wohlman, 2005; Jerez, Vitushinsky and Lavagna, 2005) have elucidated some of the intricacies of phase shifts measured in mesoscopic electron interferometers.

An additional consequence of the equivalence of the two spin transport channels is that the zero-temperature conductance through a Kondo dot is $2e^2/h$ for symmetric reservoir–dot coupling (equation (11)). In contrast, the maximum conductance on a conventional Coulomb charging peak is only e^2/h in the absence of Kondo correlations, since only one spin state can be transmitted at a time. The configuration of equal reservoir coupling and $T = B = V = 0$ is commonly referred to as *Kondo in the unitary limit*. This limit can be achieved experimentally as long as k_BT, eV, $g\mu_BB \ll k_BT_K$ and the coupling asymmetry is small compared to Γ, as observed by van der Wiel *et al.* (2000).

3 KONDO EFFECT IN MODIFIED ENVIRONMENTS

In the previous section, we briefly discussed how the Kondo state is suppressed by external perturbations such as temperature and magnetic field. In this section, we provide a more general description of how the spin-1/2 Kondo state evolves in response to modified environments.

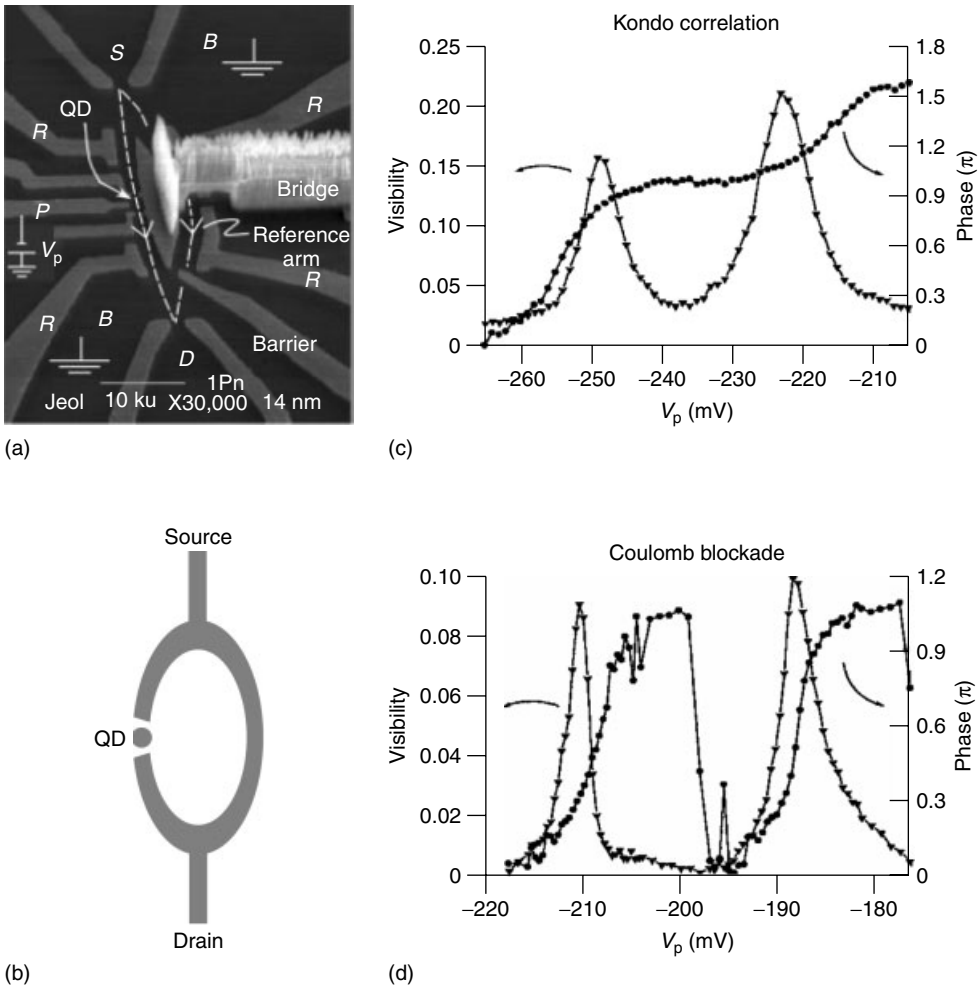

Figure 9. (a) SEM image of a mesoscopic Aharonov–Bohm interferometer with (Reproduced from Y. Ji *et al*., 2000, with permission from Science AAAS. © 2000) (b) a rough schematic of the device. (c) Evolution of the transmission phase and interference visibility as a function of the quantum dot energy level in the Kondo regime. The phase shift plateaus at π in the middle of the Kondo valley before rising to 1.5π when the quantum level is doubly occupied. (Reproduced from Y. Ji *et al*., 2000, with permission from Science AAAS. © 2000.) (d) In the Coulomb blockade regime ($T_K < T_{base}$), the phase shift increases and then falls by π each time the quantum dot occupancy is increased by one electron. (Reproduced from Y. Ji *et al*., 2000, with permission from Science AAAS. © 2000.)

In addition to temperature, magnetic field, and bias, nonideal conduction reservoirs and other external couplings can affect the Kondo behavior. The effects of perturbations on the Kondo state can be categorized as follows: (i) the Kondo state is suppressed because of the decoherence of the Kondo singlet (e.g., suppression of Kondo by thermal fluctuations), (ii) a non-Kondo ground state becomes the lowest-energy ground state (e.g., formation of spin-polarized ground state in high magnetic field), or (iii) a new Kondo state is created. The Kondo energy scale ($k_B T_K$) is a useful scale for determining how a perturbation will affect the Kondo state. Weak perturbations ($E < k_B T_K$) typically only partially suppress the Kondo state, while stronger perturbations ($E > k_B T_K$) are needed to significantly alter or destroy the Kondo singlet.

3.1 Decoherence of the Kondo state

We first discuss how various processes can lead to decoherence of the Kondo singlet. The Kondo singlet state is created by spin-flip cotunneling processes between conduction electrons and the local state. Non-Kondo processes, such as emission or absorption of a phonon or photon, disturb the necessary superposition of electronic states in the Kondo singlet. At zero temperature and bias, the phase space available for these non-Kondo processes is nearly eliminated and delocalized electrons within length ξ_K (equation (7)) form a Kondo singlet with the local spin. At finite temperature, thermal fluctuations drive non-Kondo transitions, progressively destroying these correlations. These non-Kondo transitions are facilitated by smearing of the sharp Fermi

distribution of the leads with temperature, which increases the available phase space for the transitions. Similarly, a small bias ($eV < k_B T_K$) applied across the dot also opens up phase space for non-Kondo transitions, leading to a suppression of the Kondo state. Larger biases have a more profound affect on the Kondo state, as discussed later in this section.

Coupling the quantum dot to other noise sources can have similar decohering effects. Avinun-Kalish *et al*. (2004) experimentally investigated the suppression of the Kondo state due to a capacitively coupled QPC. Conceptually, the QPC can be treated either as a source of shot noise or as a quantum dot charge measurement device, as discussed in Section 2.3.1. The authors observed stronger-than-expected suppression of Kondo transport, which they attributed to the long residence time of an electron in the Kondo cloud that extends well into the leads (Avinun-Kalish *et al*., 2004). The Kondo state can also be decohered by irradiating the sample with microwave radiation (Kaminski, Nazarov and Glazman, 1999; Elzerman *et al*., 2000). Here the random population and decay of excited states by photons takes over the role of thermal fluctuations in destroying the Kondo state.

3.2 Nonequilibrium Kondo effect

An applied bias across the quantum dot can have several interesting consequences on the Kondo state. For a quantum dot coupled equally to two leads at the same potential, the Kondo screening cloud spans both leads. An applied bias between the leads exposes the quantum dot to different Fermi levels, which opens up inelastic (decohering) channels for electron scattering between different leads. Kondo exchange with each individual lead, however, is not affected. For biases above $k_B T_K$, the Kondo spectral function splits into two resonances centered on the Fermi energies of each reservoir, as shown in Figure 10(a) (Wingreen and Meir, 1994; Schiller and Hershfield, 1995). The two Kondo resonances slowly fade with increasing bias because of decoherence associated with the exchange of electrons between the leads, but they remain visible for biases far exceeding $k_B T_K$. Two-terminal quantum dot measurements cannot accurately map out the nonequilibrium spectral function, but instead measure a convolution of two evolving spectral functions. The splitting can be observed experimentally through the addition of a weakly coupled third lead (Lebanon and Schiller, 2001; Leturcq *et al*., 2005), as shown in Figure 10(b). An alternative approach to probing the out-of-equilibrium Kondo spectral function has been investigated using a split Fermi distribution in a quantum wire side-coupled to a quantum dot (de Franceschi *et al*., 2002).

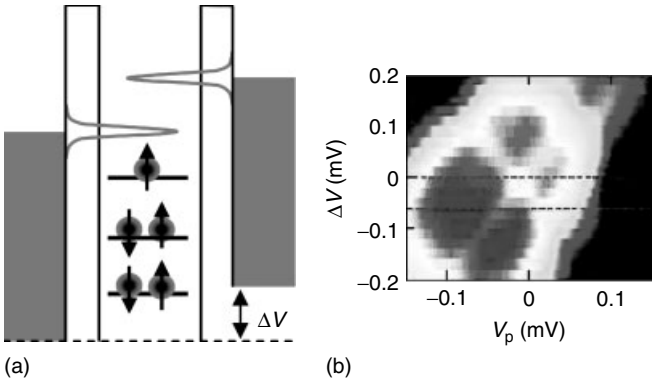

Figure 10. (a) A schematic of the splitting of the Kondo spectral function with an applied bias. The relative amplitude of the Kondo resonance in each lead depends on the respective dot–lead coupling. In the extreme case, where one lead is well coupled and the other is weakly coupled (typical of STM experiments), the weakly coupled lead can be treated as a spectroscopic probe (Lebanon and Schiller, 2001; Nagaoka, Jamneala, Grobis and Crommie, 2002). (b) The splitting of the Kondo resonance with applied bias can be probed by weakly coupling an additional lead. The plot shows the current through the weakly coupled lead as a function of the voltage difference (ΔV) between the two strongly coupled leads. A Kondo conductance enhancement is observed when the Fermi energy of the weakly coupled lead is aligned with the Fermi energy of either one of the strongly coupled leads, leading to the cross pattern seen in the figure. (Reproduced from R. Leturcq *et al*., 2005, with permission from the American Physical Society. © 2005.)

3.2.1 Recovery of the Kondo state

An applied bias can also provide the necessary energy to form a Kondo singlet when the Kondo ground state is not otherwise the favored configuration. The first example of this phenomenon is the recovery of the Kondo effect at finite bias in an applied magnetic field. A magnetic field breaks the spin degeneracy of the quantum dot ground state favoring a spin-polarized ground state over the Kondo singlet. As a result, spin-flip transitions incur an energy cost, leading to a characteristic suppression of Kondo conductance, as described in Section 2.3.2. The spin-flip energy cost can be compensated by applying a bias across the quantum dot. Here, the Kondo state reemerges when the applied bias is equal to the spin-flip energy ($eV \sim g\mu_B B$) (Goldhaber-Gordon *et al*., 1998a; Cronenwett, Oosterkamp and Kouwenhoven, 1998; Kogan *et al*., 2004a). Experimentally, this produces two Kondo peaks, separated by twice the spin-flip energy (Figure 11). Surprisingly, the measured splitting of the Kondo resonance exceeds the expected Zeeman splitting, an effect which is not fully understood (Kogan *et al*., 2004a; Costi, 2000; Moore and Wen, 2000).

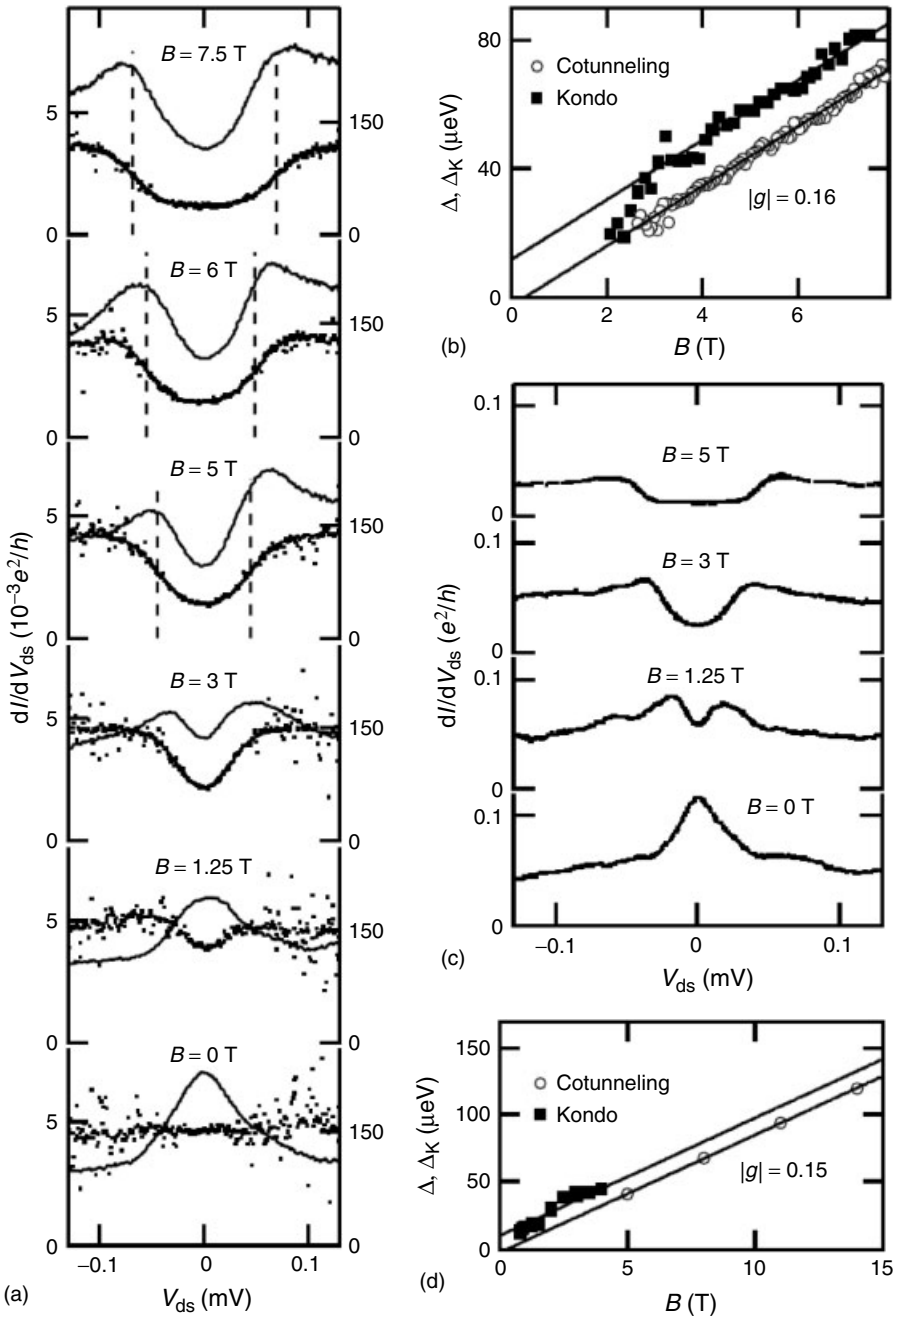

Figure 11. Evolution of the Kondo resonance and the inelastic spin-flip cotunneling gap with applied magnetic field for two different quantum dot devices. Device 1: (a) The solid line (dots) shows the evolution of the Kondo peak (cotunneling gap) with applied field. (b) The Kondo peak splitting ($2\Delta_K$, solid squares) is larger than the spin-flip cotunneling gap (2Δ, open circles), indicating that $\Delta_K > g\mu_B B$. Device 2: (c) The split Kondo peak seamlessly evolves into an inelastic spin-flip cotunneling signal as the magnetic field is increased. (d) The transition to inelastic cotunneling is marked by a decrease in the measured gap, indicating again that $\Delta_K > g\mu_B B$. (Reproduced from A Kogan *et al*., 2004, with permission from the American Physical Society. © 2004.)

High-frequency microwave radiation ($hf > k_B T_K$) can break up the Kondo singlet and destroy the Kondo effect, as described previously. On the other hand, microwave radiation can also drive Tien–Gordon photon-assisted tunneling processes (Kouwenhoven *et al*., 1994). By tuning the applied bias to the photon energy ($eV \sim hf$), a unique Kondo state can exist in which coherent spin-flip tunneling events coincide with simultaneous absorption or emission of photons. Kogan and coworkers found that such a state can be achieved experimentally if the monochromatic microwave radiation

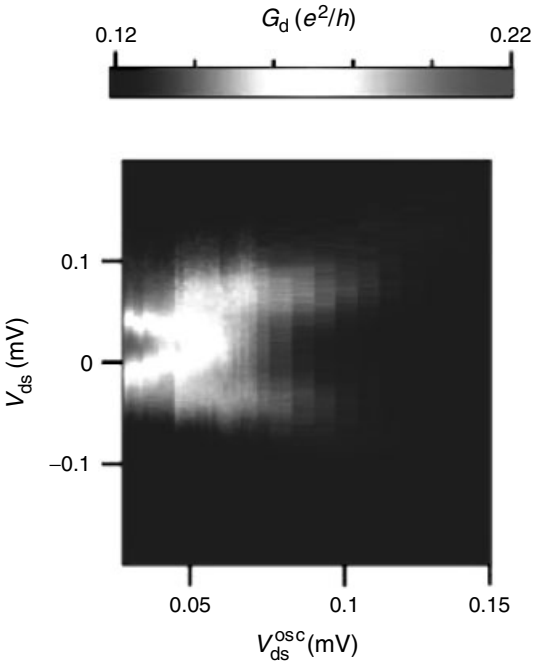

Figure 12. Splitting of the Kondo peak as a function of microwave irradiation amplitude. (Reproduced from A. Kogan *et al*., 2004, with permission from Science AAAS. © 2004.)

intensity is tuned so that $eV_{osc} \sim hf$ (Kogan, Amasha and Kastner, 2004b). These conditions ensure that the photon field is strong enough to modify Kondo processes, but not strong enough to decohere them altogether. The experimental signature of this state is a splitting of the Kondo peak into two peaks separated by twice the photon frequency, as seen in Figure 12.

3.2.2 Crossover to cotunneling

In the examples of nonequilibrium Kondo effects presented here, a finite bias is essential for the creation of the Kondo state even though it also introduces decoherence processes. Inevitably, the Kondo state will decohere completely when exposed to strong enough perturbations ($E \gg k_B T_K$). Incoherent, or inelastic, cotunneling processes can still enhance conductance in this regime, though to a much lesser extent than the analogous coherent processes that compose the Kondo effect (de Franceschi *et al*., 2001). The transition from coherent Kondo tunneling to incoherent cotunneling has been investigated by several groups (Sasaki *et al*., 2000; Kogan *et al*., 2004a). Figure 11(c) and (d) shows the seamless transition from Kondo to incoherent cotunneling as a function of an applied magnetic field (Kogan *et al*., 2004a; Heinrich, *et al*., 2004).

3.3 Kondo in Landau levels

Though an applied magnetic field generally suppresses the Kondo state, several novel Kondo states can form at intermediate fields. The electronic states of a 2DEG in magnetic fields are Landau levels (LLs), which for our purposes are circular orbits at quantized multiples of the cyclotron energy. Quantum dot states can acquire an LL character once the electron cyclotron radius is comparable to the spatial dimensions of the dot. The quantum dot LL states behave in much the same way as regular quantum dot states and can exhibit Kondo behavior (Schmid, Weis, Eberl and von Klitzing, 2000; Sprinzak *et al*., 2002; Stopa *et al*., 2003; Keller *et al*., 2001). Typically, the lowest spin-degenerate LL is most strongly coupled to the leads, and Kondo processes occur when this level contains an unpaired spin (Stopa *et al*., 2003; Keller *et al*., 2001). The occupancy of the LL can be tuned by changing the total number of electrons with an applied gate voltage or by redistributing the existing electrons among the LLs using an applied magnetic field. As a result, the Kondo conductance shows a 'checkerboard' pattern as a function of gate voltage and magnetic field, as shown in Figure 13 (Schmid, Weis, Eberl and von Klitzing, 2000; Sprinzak *et al*., 2002; Stopa *et al*., 2003; Keller *et al*., 2001). At higher magnetic fields, the Zeeman splitting spin polarizes the leads, and the Kondo conductance vanishes. In high magnetic fields, electrons can form closed orbits around a depleted region of a 2DEG. The resulting 'antidot' can act as a magnetic impurity and exhibit the Kondo effect (Kataoka, Ford, Simmons and Ritchie, 2002).

3.4 Modified conduction reservoir

In order for Kondo correlations to persist, the quantum dot must be able to freely exchange electrons with the leads. Metallic leads facilitate electron exchange by providing a large smooth density of states near the Fermi level. However, distinctive Kondo states can exist even if the leads have additional electronic structure.

3.4.1 Finite level spacing (Kondo box)

A natural question to ask is what happens to Kondo processes when the mean level spacing of the leads (Δ) becomes comparable to the Kondo temperature (T_K) (Thimm, Kroha and von Delft, 1999; Simon and Affleck, 2002). Thimm, Kroha, and von Delft (1999) explored this question theoretically in the context of a single-electron transistor and found three unique signatures: (i) the Kondo resonance splits up into a series of subpeaks, (ii) the conductance depends on the even/odd occupancy of the combined lead–quantum dot

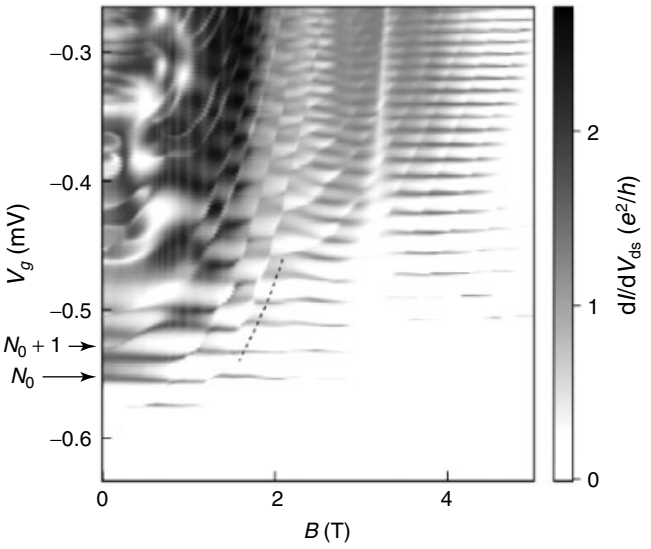

Figure 13. In a high magnetic field applied perpendicular to the quantum dot, the states of a quantum dot organize into Landau levels. If the dot is strongly coupled to its leads, the Kondo effect occurs whenever the occupancy of the outer Landau level (LL) is odd. As a result, the differential conductance shows a checkerboard pattern as the LL occupancy can be tuned by both a gate voltage and the magnetic field. (Reproduced from J. Weis *et al*., 2000, with permission from the American Physical Society. © 2000.)

system, and (iii) quantum dot transport exhibits Fano-like line shapes with anomalous temperature dependence. A 'Kondo box' exhibiting these features has yet to be quantitatively studied experimentally despite several interesting approaches (Odom, Huang, Cheung and Lieber, 2000; Manoharan, Lutz and Eigler, 2000; Booth *et al*., 2005).

3.4.2 Magnetic leads

Ferromagnetic leads create spin imbalances, which affect the dynamics of Kondo spin-flip exchange. The behavior of these systems depends on the relative magnetic orientation of the two leads connected to the quantum dot (Sergueev *et al*., 2002; Martinek *et al*., 2003; Choi, Sánchez and López, 2004). If both leads have the same magnetic orientation, the reservoir spin imbalance acts similar to a magnetic field. Here, the Kondo spectral function is suppressed and split, whenever the quantum dot is not electron–hole symmetric ($\varepsilon_0 \neq -U/2$) (Choi, Sánchez and López, 2004). The Kondo effect for antiparallel magnetic lead alignment is equivalent to the nonmagnetic case, though with a different nonequilibrium behavior. Experimental realizations of ferromagnetic coupled leads in mesoscopic systems have been hampered by the difficulty in reliably creating magnetic semiconductor structures. Some of the predicted magnetic behavior has been seen, however, in single molecular transistors (Pasupathy *et al*., 2004).

3.4.3 Superconducting and Luttinger-liquid leads

More exotic systems have also been considered, such as coupling a quantum dot to superconducting (Fazio and Raimondi, 1998; Sun, Guo and Lin, 2001) or Luttinger-liquid leads (Kane and Fisher, 1992; Lee and Toner, 1992; Furusaki and Nagaosa, 1994). In both cases, the leads have no density of single-electron states at the Fermi level, where the Kondo screening cloud would normally form. Therefore, the Kondo ground state competes with the native ground state of the leads. For superconducting leads, the Kondo effect will develop if the Kondo energy scale, $k_B T_K$, exceeds the superconducting single-electron excitation energy gap, Δ, as seen experimentally in carbon nanotube quantum dots (Buitelaar, Nussbaumer and Schönenberger, 2002). Kondo behavior in Luttinger liquids depends sensitively on the Luttinger parameter of the leads (Komnik and Gogolin, 2003), but has not been examined in mesoscopic experiments.

4 EXOTIC KONDO SYSTEMS

The Kondo effect, as described by the Anderson model (equation (1)), arises when a localized degenerate state is coupled to a reservoir of conduction electrons. Though our discussion has focused on spin-1/2 degeneracy, the Kondo effect can also arise from a twofold degeneracy with other physical origins (Figure 14), or from a higher local degeneracy. In this section, we review recent mesoscopic systems that demonstrate such scenarios.

4.1 Nonspin Kondo systems

4.1.1 Twofold electrostatic degeneracy

One of the most striking examples of a non-spin-1/2 Kondo system is the spinless Kondo effect observed in a capacitively coupled double quantum dot system (Wilhelm, Schmid, Weis and von Klitzing, 2002). The experimental configuration (shown in Figure 15a) consists of two parallel quantum dots, each coupled to its own independent set of leads. The two dot–lead systems cannot exchange electrons with each other, but can communicate via electrostatic coupling between the two quantum dots. A charge degeneracy can be created by tuning the two quantum dots so that the quantum state corresponding to having an extra electron on

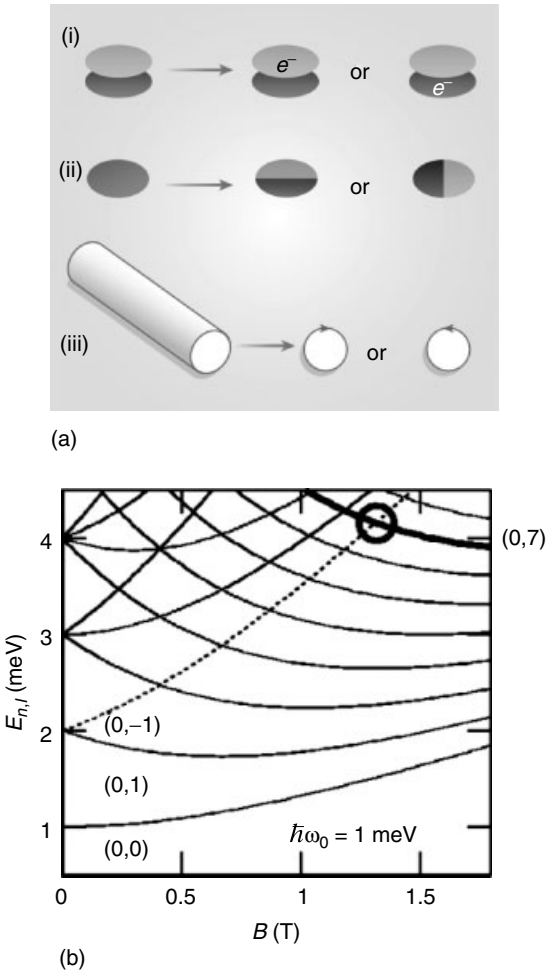

Figure 14. (a) The spin-1/2 Kondo effect stems from the twofold spin degeneracy of a quantum dot level. Degeneracies with origins other than spin can also lead to a completely equivalent Kondo effect. Such degeneracies can arise from the following: (i) two spatially separated sites of which only one can be occupied due to Coulomb repulsion, (ii) a spatial symmetry that leads to two degenerate orbitals, and (iii) the lattice symmetry of a carbon nanotube which gives rise to a twofold orbital degeneracy. (Reproduced from Ronald M. Potok *et al*., 2005, with permission from Nature Publishing Group. © 2005.) (b) Orbitals with different energies can be made degenerate by tuning their energies with an applied magnetic field. Shown here is the evolution of circular quantum dot states with magnetic field. Degeneracies occur at level crossings, such as the one indicated by the circle. (Reproduced from S. Sasaki *et al*., 2004, with permission from the American Physical Society. © 2004.)

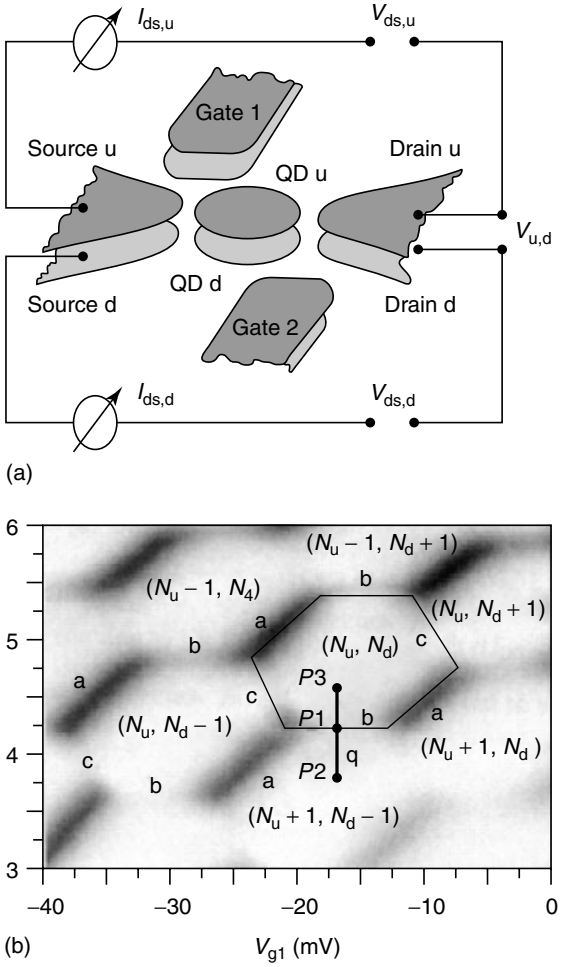

Figure 15. (a) Schematic of a capacitively coupled double quantum dot system used to observe the spinless Kondo effect (scenario (i) in Figure 14(a)). (b) Current through the upper quantum dot as a function of V_{G1} and $V_{u,d}$ shows a honeycomb pattern because of electrostatic interaction with the lower quantum dot ($V_{DS,u} = 80\,\mu$V; 'white' = no current). The spinless Kondo effect leads to the faint conductance observed along the line marked 'b'. (Reproduced from U. Wilhelm *et al*., 2002, with permission from Elsevier. © 2002.)

dot 1 ($N_1 + 1$, N_2) is degenerate with the state corresponding to an extra electron on dot 2 (N_1, $N_2 + 1$). This charge degeneracy takes over the role normally played by spin degeneracy, mapping this system onto the Anderson impurity model (Pohjola *et al*., 2000; Wilhelm, Schmid, Weis and von Klitzing, 2001).

Transport through one of the dots as a function of the occupancy of both dots reveals a honeycomb pattern (Figure 15b), similar to that seen in transport through double quantum dot systems (van der Wiel *et al*., 2003). The faint conductance feature on side b of the hexagon in Figure 15(b) (at the charge degeneracy point described earlier) is the feature of interest in this experiment. While single-electron transport is forbidden because of CB, two-electron processes give rise to nonzero conductance. Here an electron jumps off one dot, while another electron simultaneously jumps onto the other. These processes drive the Kondo effect, screening the electrostatic (as opposed to magnetic) degeneracy and giving rise to a nonzero conductance.

4.1.2 Twofold orbital degeneracy

A more common nonspin degeneracy in quantum dot systems is orbital degeneracy, which typically arises from spatial symmetries. The orbital Kondo effect has been observed in a circular quantum dot (Sasaki *et al*., 2004). Carbon nanotubes have an intrinsic orbital degeneracy due to their structure, and several groups have reported Kondo effects stemming from this degeneracy (Nygård, Cobden and Lindelof, 2000; Jarillo-Herrero *et al*., 2005a,b). Nondegenerate orbital states can be brought into degeneracy by applying a magnetic field, as shown in Figure 14(b), leading to analogous Kondo effects (Sasaki *et al*., 2004). Spin degeneracy may also combine with orbital degeneracy, leading to exotic Kondo physics as described in the following subsections.

4.2 Multiple-degeneracy Kondo systems

Quantum dots with a multiple degenerate grounds state can exhibit a variety of interesting Kondo effects. The Kondo behavior of these systems depends on the allowed transitions between the N degenerate states. If transitions can occur equally between any pair of degenerate states, the system has $SU(N)$ symmetry and is described by the Coqblin–Schrieffer model (Coqblin and Schrieffer, 1969). The Kondo temperature is predicted theoretically to be larger in these systems than in equivalent spin-1/2 Kondo systems and depends exponentially on N:

$$T_K \sim D e^{-1/N\rho(E_F)J} \tag{12}$$

where J, $\rho(E_F)$, and D are the exchange coupling, density of states, and interacting electron bandwidth, respectively. Like the spin-1/2 Kondo ground state, the $SU(N)$ Kondo ground state is no longer degenerate. In contrast, for an impurity with a high spin degeneracy ($S > 1/2$), a single conduction channel will only couple states with $\Delta S_z = 1$. In these systems, the Kondo effect will underscreen the magnetic moment, leaving behind a ground state of lower degeneracy, associated with a net spin reduced by 1/2 from its native value (Mattis, 1967). Other systems, such as the singlet–triplet degeneracy discussed later, can have a more complicated coupling structure (Eto, 2005).

4.2.1 Spin and orbital degeneracy: SU(4) Kondo effect

When the electronic state of a system contains both orbital and spin degeneracy, the same delocalized lead electrons that magnetically screen the unpaired spin may also electrostatically screen the orbital degeneracy. The two degrees of freedom can produce an $SU(4)$ Kondo effect, which has been observed in vertical GaAs dots (Sasaki *et al*., 2004) and carbon nanotubes (Jarillo-Herrero *et al*., 2005b). In the vertical quantum dot system, T_K is not large enough for the spin-1/2 Kondo effect to be observed in the absence of orbital degeneracy (odd valleys in Figure 16a). Kondo conductance enhancement is observed, however, when the dot is tuned to an orbital crossing point using an applied magnetic field. Here an $SU(4)$ fourfold degeneracy is present,

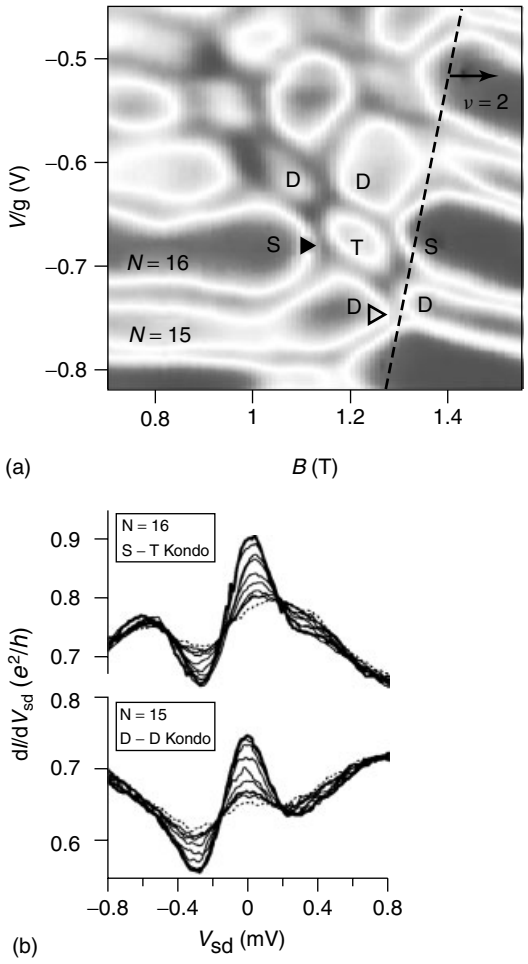

Figure 16. (a) Zero-bias conductance measured in a vertical quantum dot as a function of gate voltage and magnetic field. Orbital states are brought into and out of degeneracy by the magnetic field, which leads to two types of Kondo effects. For odd occupancy, a doublet–doublet (D–D) Kondo effect arises at orbital crossings where a fourfold degeneracy is present. A singlet–triplet (S–T) Kondo effect occurs at level crossings for even occupancy. To the right of the dotted line, all electrons occupy the lowest Landau level. (b) The temperature dependence of the Kondo resonance for the S–T and D–D Kondo effects from 60 mK (thick solid line) to 1.5 K (dashed line). Both systems show a similar Kondo temperature. (Reproduced from S. Sasaki *et al*., 2004, with permission from the American Physical Society. © 2004.)

which enhances the Kondo temperature (Eto, 2005). This 'doublet–doublet' Kondo state produces a zero-bias Kondo peak, as seen in Figure 16(b).

Carbon nanotubes have an intrinsic orbital degeneracy in addition to a spin degeneracy, which can lead to $SU(4)$ Kondo physics (Jarillo-Herrero *et al.*, 2005b). Owing to electron–hole symmetry, the $SU(4)$ Kondo effect is observed when the two orbitals are occupied by either one or three electrons (Figure 17a). The fourfold degeneracy responsible for the Kondo ground state is demonstrated by the splitting of the Kondo resonance into four peaks with magnetic field (Figure 17b). The magnetic field suppresses the $SU(4)$ Kondo effect by first lifting the orbital degeneracy. The resulting spin-1/2 Kondo effect survives until the Zeeman splitting becomes comparable to the Kondo temperature. A pure orbital $SU(2)$ Kondo effect is attained at orbital level crossings, which one can attain by applying a magnetic field (dashed lines in Figure 17a). In these experiments, the Kondo temperature for the $SU(4)$ Kondo effect is larger than the Kondo temperature for the $SU(2)$ Kondo effect, as predicted by equation (12). It is not yet clear why the electrons in the (metal) leads have the requisite fourfold symmetry to fully screen the local state on the nanotube.

4.2.2 *Triplet and singlet–triplet Kondo effect*

The ground state of a quantum dot with an even number of electrons is usually a spin singlet at zero magnetic field, where each occupied orbital contains a pair of electrons. The triplet state will have lower energy, however, if the exchange energy gained for parallel spin filling exceeds the level separation between adjacent orbitals (Tarucha *et al.*, 2000). A quantum dot with $S = 1$ no longer has the same spin symmetry as the spin-1/2 reservoir electrons. As discussed earlier, Kondo correlations will partially screen the $S = 1$ quantum dot, leaving behind a residual spin-1/2, as long as only a single reservoir mode is coupled to the quantum dot. Perhaps owing to a low T_K predicted for these systems (Wan, Phillips and Li, 1995; Izumida, Sakai and Shimizu, 1998), a pure spin-1 Kondo effect has not been unambiguously observed in mesoscopic systems.

Alternatively, the singlet and triplet state can be brought into degeneracy using an applied magnetic field. At low magnetic fields, the Zeeman splitting of the triplet is negligible and the singlet–triplet degeneracy point is fourfold degenerate, though not $SU(4)$ symmetric (Eto and Nazarov, 2000; Pustilnik and Glazman, 2000). The singlet–triplet Kondo temperature is expected to be higher than for spin-1/2 Kondo systems and comparable to that found in $SU(4)$ Kondo systems (Eto, 2005). A singlet–triplet Kondo effect has been observed in transport measurements through vertical quantum dots (Sasaki *et al.*, 2000, 2004) (shown in Figure 16), lateral quantum dots (Schmid, Weis, Eberl and von Klitzing, 2000; van der Wiel *et al.*, 2002; Kogan *et al.*, 2003), and carbon nanotubes (Nygård, Cobden and Lindelof, 2000; Jarillo-Herrero *et al.*, 2005a,b) (Figure 17a). Even if the singlet and triplet states are not energetically degenerate, a finite bias can compensate for the energy difference and lead to a nonequilibrium singlet–triplet Kondo effect, as seen recently in a carbon nanotube quantum dot (Paaske *et al.*, 2006).

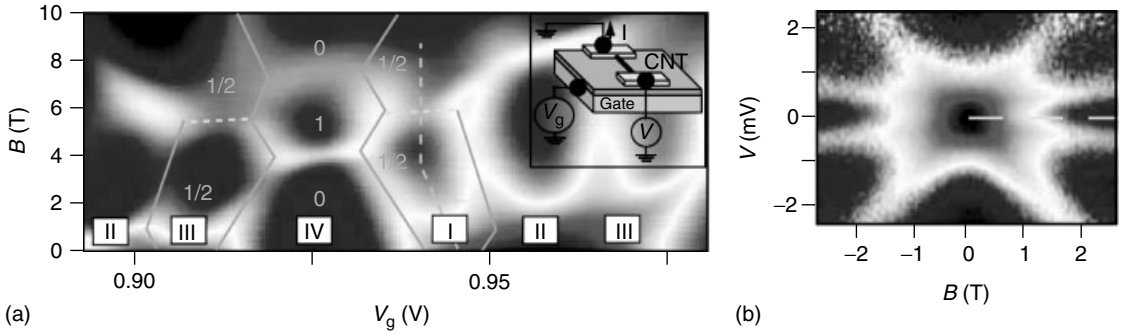

Figure 17. (a) Conductance through a carbon nanotube quantum dot (shown schematically in the inset) as a function of magnetic field (B) and gate voltage (V_G). The solid lines highlight the evolution of the Coulomb blockade peaks with B. The Roman numerals indicate the number of electrons occupying the partially occupied four-electron shell at $B = 0$, while the Arabic numbers represent the spin of the ground state. At $B = 0$, an $SU(4)$ Kondo effect occurs for single (I) and triple occupancy (III), while a singlet–triplet Kondo effect is observed for double occupancy (II). A purely orbital Kondo effect is observed at magnetic-field-induced level crossings, as indicated by the horizontal dotted lines. (b) A magnetic field will split the four degenerate states (two spin × two orbital) that generate the $SU(4)$ Kondo effect. Since the orbital magnetic moment is approximately three times larger than the spin magnetic moment in a carbon nanotube, the orbital states are split at a different rate than the spin states, and four peaks are observed at finite B field. 4.2.3 Two-stage Kondo effect

A system on the border of a singlet–triplet transition can exhibit a remarkable two-stage Kondo effect. If coupled to two reservoir modes, the transport properties of an $S = 1$ quantum dot are theoretically predicted to have a nonmonotonic dependence on temperature and bias (Pustilnik and Glazman, 2001). The two modes create two different Kondo screening channels with different associated Kondo temperatures, T_{K1} and T_{K2}. At unitary coupling, the two modes interfere and reduce Kondo conductance when T is below both T_{K1} and T_{K2}. A second screening channel can form in systems containing only one tunneling mode if the dot–lead couplings are asymmetric (Pustilnik and Glazman, 2001). A quantum dot just on the singlet side of the singlet–triplet transition is also predicted to undergo a similar two-stage Kondo effect, even if only a single tunneling mode is coupled to the dot (Hofstetter and Schoeller, 2002). Such two-stage Kondo effects have been observed in lateral quantum dots (van der Wiel *et al*., 2002; Granger *et al*., 2005). In experiments by van der Wiel, a magnetic field tunes the quantum dot near a singlet–triplet degeneracy point. Conductance measurements show a dip in the zero-bias anomaly at low temperatures (Figure 18). From the available data, it is not possible to unambiguously distinguish whether a singlet or triplet ground state is responsible for the observed effect.

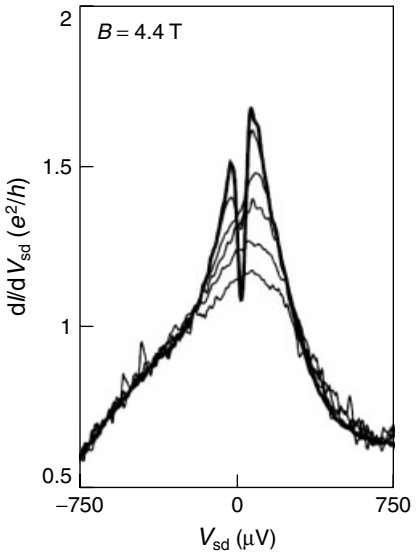

Figure 18. The two-stage Kondo effect is characterized by enhanced conductance at intermediate energies and suppressed conductance at low energies, as demonstrated by the dip in the zero-bias Kondo resonance. Shown here is the temperature dependence of the Kondo peak from 15 mK (solid line) to 800 mK. (Reproduced from W.G. van der Wiel *et al*., 2002, with permission from the American Physical Society. © 2002.)

5 RECENT DEVELOPMENTS AND FUTURE DIRECTIONS

As we have seen, the designability and *in situ* control of parameters in semiconductor quantum dots have enabled highly quantitative tests of Kondo physics and observation of Kondo effects in new regimes and scenarios. This new approach has brought fresh insight and excitement to what was legitimately considered one of the best-understood phenomena in solid-state physics. The continuing flow of theoretical predictions and experimental investigations – around 100 papers per year in mesoscopic physics alone – attests that Kondo physics remains a rich and vibrant field. We conclude our review with a few remarks about the future of mesoscopic Kondo experiments, as suggested by recent trends.

5.1 Spatial and temporal Kondo physics

Mesoscopic experiments have illuminated the effect on Kondo transport of external parameters (e.g., temperature, magnetic field) and dot–lead coupling. In short, spin-1/2 Kondo phenomenology is broadly well understood. However, several important issues remain on the cutting edge: How do a pair of magnetic impurities interact (Jeong, Chang and Melloch, 2001; Craig *et al*., 2004; Simon, Lopez and Oreg, 2005; Vavilov and Glazman, 2005)? What are the dynamics and spatial extent of the Kondo screening cloud (Sorensen and Affleck, 1996; Nordlander *et al*., 1999) and how do these depend on the dimensionality of the screening reservoirs (Simon and Affleck, 2002)? How can we understand and control the processes that lead to decoherence of the Kondo state, especially out of equilibrium (Avinun-Kalish *et al*., 2004; Kogan *et al*., 2004a; Leturcq *et al*., 2005)?

5.2 Novel Kondo systems

As discussed in Sections 3 and 4, design of a quantum dot's states has enabled studies of a broad family of Kondo effects with different local degeneracies. However, several proposed exotic Kondo systems have not yet been addressed by extensive experiments. Controlling the electronic properties of the conduction reservoir, as discussed in Section 3.4, has proved difficult in mesoscopic systems. Manipulating the coupling of quantum dots to superconducting, magnetic, or one-dimensional leads will be exciting and is likely to advance fastest in hybrid molecular-metal systems, in which the material of the metal leads can be selected to yield desired electronic structure (Buitelaar, Nussbaumer

and Schönenberger, 2002; Pasupathy *et al*., 2004). Tantalizing theoretical predictions abound for multichannel Kondo systems, such as the two-channel Kondo effect (Cox and Zawadowski, 1998; Matveev, 1995; Oreg and Goldhaber-Gordon, 2003; Pustilnik, Borda, Glazman and von Delft, 2004), which occurs when two reservoirs independently attempt to screen a spin-degenerate state. The resulting frustrated system is predicted to exhibit both local non-Fermi liquid behavior and a model quantum phase transition, as recently observed by some of the present authors in a novel double-dot geometry (Potok *et al*., 2007). This offers hope that the tools of mesoscopic physics can bear on complex correlated electrons systems normally realized only in bulk systems. Finally, several experimental observations indicate that the celebrated 0.7 structure seen in QPC transport might have Kondo origins (Cronenwett *et al*., 2002; Rejec and Meir, 2006). This effect is yet to be fully understood and should continue to attract both experimental and theoretical attention.

NOTES

[1] Though the terms *tunneling channels* and *tunneling modes* are often used interchangeably, we will avoid using the former to avoid confusion with the concept of independent Kondo screening channels, which lead to the multichannel Kondo effect (Section 5.2).

[2] In the mixed-valence regime, the Kondo resonance is expected to move away from E_F and no longer be symmetric about its maximum (Costi, Hewson and Zlatic, 1994; Wahl *et al*., 2004).

Ferromagnetic Manganite Films

Vasily Moshnyaga and Konrad Samwer
Universität Göttingen, Göttingen, Germany

1 INTRODUCTION

As a starting point in the history of perovskite manganites one should note 1950 as the year in which Jonker and van Santen (1950) published the first paper on mixed valent manganites with perovskite structure and composition $La_{1-x}Ae_xMnO_3$ (Ae = Ca, Sr, Ba). They demonstrated for the first time the existence of positive or ferromagnetic (FM) exchange interaction between Mn^{3+} and Mn^{4+} ions in an oxide compound and found optimal compositions $x = 25–40\%$ to obtain maximum values of Curie temperatures, T_C, and magnetization close to saturation.

However, it has taken a long time up to the last decade of the twentieth century, when the discovery of the high-T_C superconductivity in perovskite cuprates (Bednorz and Müller, 1986) and related huge progress in oxide thin-film technologies have renewed a great interest in other oxide systems, including perovskite manganites. In 1993, the so-called colossal magnetoresistance (CMR) was discovered in thin manganite films (von Helmolt *et al*., 1993; Chahara, Ohno, Kasai and Kozono, 1993). The effect, quantified as difference between the resistance in zero (ambient) field, $R(0)$, and the resistance in applied field, $R(B)$, normalized to $R(B)$, that is, $CMR = 100\% \times \{[R(0) - R(B)]/R(B)\}$, can be extremely large: $CMR = 10^5–10^8\%$ (McCormack *et al*., 1994). This means that electrical resistance of a magnetic material can drop by few orders of magnitude by applying an external magnetic field $B \sim 5\,T$. The discovery of the CMR effect has initiated a boom both in fundamental and technological research in the nineties.

During the past few years, perovskite manganites examine the second renaissance, which is naturally connected with great progress in nanoscience and nanotechnology. It was observed experimentally (Uehara, Mori, Chen and Cheong, 1999) and also argued theoretically (Moreo, Yunoki and Dagotto, 1999) that the electronic properties of manganites may be spatially inhomogeneous. Metallic and insulating electronic phases can coexist within the same sample of a definite chemical composition over different length scales: from micrometer down to few nanometers. The mesoscopic, nanometer-scale, electronic inhomogeneities might be interesting for the future nanotechnology – self-organized nanostructures with different functionality may be created within a chemically homogeneous medium (Mathur and Littlewood, 2003). Closely connected to the preceding issue are nanostructured manganite films and manganite-based nanocomposites. Reduced dimensions of manganites as well as novel architecture and second-phase counterpartners in composites offer additional opportunity to control the magnetotransport. Therefore, thin manganite films and corresponding thin-film technologies become important also for fundamental research because they allow creation of some specific conditions, like negative pressure (Moshnyaga *et al*., 2003), which cannot be

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

realized in bulk samples and single crystals. In summary, immense and continuous research interest in the perovskite manganites is directly related to their complexity: they possess a number of crystallographic, electronic, and magnetic phases. These phases are not 'static', they can interact with each other as well as can be strongly influenced by external factors (temperature, pressure, magnetic field, electromagnetic radiation), yielding very interesting and potentially useful effects.

The chapter is organized in the following way. In Section 2, crystalline structure, the phase diagram, and phase transitions in perovskite manganites are discussed. Moreover, experimental evidences and theoretical ideas on the inhomogeneous electronic ground state in manganites are briefly overviewed. Special attention is paid to the lattice strain and disorder effects, which are important to understand the electronic properties of manganites. Section 3 is devoted to thin-film deposition techniques, mostly used for the preparation of multinary oxide films. Physical vapor deposition (PVD) techniques and chemical routes are compared. Moreover, the peculiarities of the structure and microstructure of manganese thin films as well as thin-film composites are reviewed. Section 4 is focused on the different magnetoresistance (MR) effects in individual manganese thin films, multilayers, and nanocomposites. CMR effect at the metal–insulator (MI) transition is discussed in relation to electronic phase separation (EPS) and percolation models. Artificially grown thin-film phase-separated systems containing second insulating phase is also discussed. Low-field MR effects in multilayers (tunneling magnetoresistance, TMR) as well as in individual epitaxial manganite films (domain–wall and anisotropic MR) may have potential for spintronics due to full spin polarization of charge carriers on the Fermi level in manganites.

2 FUNDAMENTAL ASPECTS

Since the discovery of CMR effect, the manganites are still in the focus of both fundamental and applied research. During this intense study, a few comprehensive reviews (Tokura, 2000; Coey, Viret and Molnar, 1999; Dagotto, Hotta and Moreo, 2001; Dagotto, 2003) have been published, where practically all aspects of crystalline and electronic structure as well as their relations to electronic properties and phase transitions were discussed in detail. Here, we limit ourselves to summarizing remarks on the preceding topics with a special focus on the lattice strain and cation disorder effects, which, in our opinion, are of great importance for understanding magnetotransport phenomena and different MR effects in thin manganite films.

2.1 Crystalline structure and lattice strain effects

As was revealed earlier (Jonker and van Santen, 1950), the most interesting manganites, which later were shown to possess CMR effect (von Helmolt *et al*., 1993; Chahara, Ohno, Kasai and Kozono, 1993), crystallize in ABO_3 perovskite–type structure as shown in Figure 1. The manganites can be described by the general chemical formula $Re_{1-x}Ae_xMnO_3$, where Re = La, Nd, Pr are rare-earth trivalent elements, and Ae = Ca, Sr, Ba are divalent alkali earth elements. Large three-(La) and divalent (Ca) cations, shown by green color, are located in the so-called *A-site* positions, which are 12-coordinated. The small Mn ions fill the B sites, coordinated by six oxygen atoms. The structure can be also viewed as a cubic close-packed array, formed by oxygen anions and A cations, in which Mn cations occupy octahedral interstitial sites.

A very important feature of the perovskite structure is the ability to accommodate lattice distortions by means of lowering the symmetry from the cubic one down to rhombohedral, orthorhombic, tetragonal, and monoclinic. Accommodation of lattice strain seems to be a driving force for the formation of different perovskite structural modifications with contrasting electronic behavior. There are two possible reasons for lattice distortions in the perovskite manganites. *First* is the Jahn–Teller (JT) effect (Jahn and Teller, 1937), which assumes the change of local symmetry at the Mn^{3+} ion of the isolated Mn^{3+} O_6 octahedron from cubic to tetragonal with elongation along z axis and compression in the (a, b) plane when a high spin state ($S = 2$) is realized. JT effect lifts orbital degeneracy and stabilizes electronic occupation of the lowest e_g orbital. The *second* source of lattice distortions is the size mismatch between the Re and Ae cations, occupying A-site positions. Perovskite

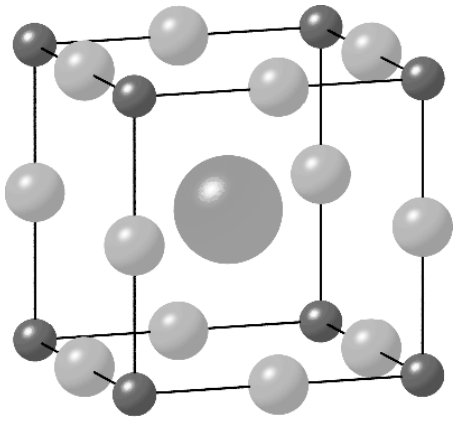

Figure 1. Fragment of perovskite structure: large Re, Ae (La, Ca) cations are shown by green color, small Mn cations (red) any oxygen anions (blue).

structure tries to expel the resulting internal or chemical pressure by corresponding cooperative rotations and tilting of MnO_6 octahedra, which form a 3D network according to orthorhombic or rhombohedral structures as shown in Figure 1.

Various perovskite structures are described by the tolerance factor, t:

$$t = (r_A + r_O)/\sqrt{2}(r_B + r_O) \tag{1}$$

where r_A and r_B are ionic radii of A and B cations, respectively, and r_O is the ionic radius of oxygen. Tolerance factor is a geometrical parameter, which quantifies the ionic size mismatch when A cation is too small to fit into the space between MnO_6 octahedra. In the cubic structure with perfect matching of (A–O) and (B–O) planes $t = 1$, which implies $r_A = r_O = 0.140\,\text{nm}$ and $r_B = (\sqrt{2} - 1)r_O = 0.058\,\text{nm}$ (Coey, Viret and Molnar, 1999). For the parent compound $LaMnO_3$ (LMO) with well-defined radius of A-site cation $r_{La} = 0.136\,\text{nm}$ and $r_{Mn^{3+}} = 0.0645\,\text{nm}$ (Shannon and Prewitt, 1976), one can get $t \approx 0.954$. This value is significantly smaller than $t = 1$ and is in accordance with observed O′-type orthorhombic structure (Urushibara *et al*., 1995). Prototypic optimally doped CMR compounds, such as $La_{0.7}$(Ca or Sr or Ba)$_{0.3}MnO_3$, which are of most interest in the present review, possess $t \approx 0.969$, $t \approx 0.979$, and $t \approx 0.997$, respectively. Thus, only the $La_{0.7}Ba_{0.3}MnO_3$ (LBMO) compound with the largest average radius of A-site cation, $\langle r_A \rangle = 0.1435\,\text{nm}$ shows the structure close to cubic. LSMO ($\langle r_A \rangle = 0.1384\,\text{nm}$) and LCMO ($\langle r_A \rangle = 0.1354\,\text{nm}$) manganites possess rhombohedral, *R-3c* (Urushibara *et al*., 1995), and orthorhombic, P_{nma} (Radaelli *et al*., 1995), structures, respectively.

A very important structural characteristic is the (Mn–O–Mn) bond angle, the value of which is close to 180° for the cubic as well as for rhombohedral structures. However, the bond angle for the orthorhombic structure becomes significantly smaller than 180° (Mitchel *et al*., 1996) and decreases continuously with decreasing tolerance factor in the region $0.89 < t < 0.96$ (Radaelli *et al*., 1997). The bond angle distortions provide a mechanism for the so-called *bandwidth control* (Hwang *et al*., 1995). It was shown that isovalent substitutions in the A-site positions, affecting both $\langle r_A \rangle$ and t values to a large extent, control the Curie temperature, T_C, and MI transition temperature, T_{MI}, in a broad range from 50 K for $t = 0.89$ up to 370 K ($t = 0.98$). Another possibility provided by the perovskite structures is the so-called *filling control*. As was shown already (Jonker and van Santen, 1950), the perovskite structure is extremely robust against chemical substitutions on the A-site positions, allowing to obtain a complete row of solid solutions like $La_{1-x}Ca_xMnO_3$ for $0 < x < 1$. Therefore, the doping by charge carriers (holes) through divalent substitutions in the A-site positions becomes available.

2.2 Phase transitions and phase diagram

Perovskite manganites, depending on their composition and structural modifications, show a rich variety of electronic phases such as metallic and insulating; ferromagnetic and antiferromagnetic; charge and orbitally ordered states. These phases interact with each other and can be strongly influenced by different external fields (temperature, magnetic field, pressure, etc.), resulting in a peculiar electronic transport and magnetic behavior.

Traditionally viewed, a parent stoichiometric compound LMO with $t = 0.954$ and orthorhombic P_{nma} structure is well known as *A-type antiferromagnet* with a Neel temperature $T_N = 140\,\text{K}$ (Wollan and Kohler 1955). The spins of Mn ions are ordered ferromagnetically within the (a, b) plane along the a axis. The sublattice moment, $3.87\,\mu_B$, is close to the spin-only contribution of the Mn ions. However, adjacent planes are ordered antiferromagnetically, yielding zero or very weak total moment. Moreover, LMO shows insulating behavior because of the localized electrons on the lowest occupied e_g orbitals of the Mn^{3+} ions due to the JT distortions of the MnO_6 octahedron. The insulating gap $E_{JT} \sim 0.25\,\text{eV}$ (Dessau and Shen, 2000) is provided by JT splitting of previously orbitally degenerated e_g states. JT distortions in LMO are coherent, that is, long and short (Mn–O) bonds alternate in a 'checkerboard' pattern leading to the so-called "cooperative JT distortion" or "orbital ordering" (OO). The OO state is characterized by ordering of the lowest occupied $3z^2 - r^2$ in a real space as shown in Figure 2 (Ishihara, Inoue and Maekawa, 1997). As was first argued by Goodenough (1955), the reason for OO is minimization of elastic strain originated due to different lengths of Mn–O bonds. The OO state becomes energetically favorable for $T_{ST} \leq 873\,\text{K}$, at which a transition from the high-temperature rhombohedral phase to the low-temperature orthorhombic phase occurs (Wold and Arnott, 1959). Note that OO phase transition takes place at much higher temperature than antiferromagnetic Neel temperature, $T_N = 140\,\text{K}$.

As we have mentioned in the preceding text, the filling control occurs by means of hole doping when a part of La cations are substituted with Ca, Sr, or Ba, forming a compound like $La_{1-x}Ca_xMnO_3$. This is equivalent to the creation of xMn^{4+} ions with $3d^3$ configuration and one hole on their e_g orbital, which can take part in charge transfer. The Mn^{4+} ion is not a JT ion in contrast to that of Mn^{3+} and can be viewed as a perturbation of the long-range OO state in LMO matrix. By increasing the doping level 'x', the OO state

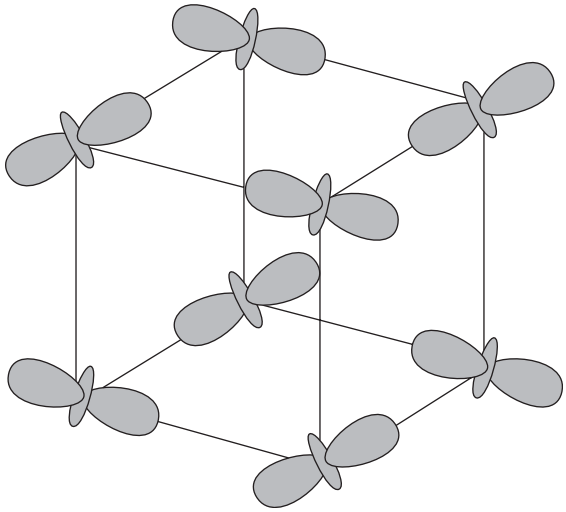

Figure 2. Ordering of $3z^2$-r^2 orbitals in $LaMnO_3$. (Reproduced from S. Ishihara *et al*., 1997, with permission from the American Physical Society. © 1997.)

will be progressively diluted and e_g holes become mobile (itinerant) dominating the charge transport by means of hopping between different Mn sites. Itinerancy of e_g electrons (holes), or strictly speaking, one-electron bandwidth, W, is provided by covalent mixing of e_g orbitals of Mn and those of 2p of oxygen (Goodenough, 1955). Another part of 3d electrons occupying the orbital triplet t_{2g} states stabilized by crystal-field splitting is localized, forming the local spin ($S = 3/2$) and being responsible for magnetic properties. Thus, the covalent character of Mn–O bonds as well as strong on-site Hund coupling between conducting e_g electrons with spin $S = 1/2$ and those of $t_{2g}(S = 3/2)$ both lead to the long-range FM ordering between Mn^{3+} and Mn^{4+} ions via the so-called *double exchange* (*DE*) interaction (Zener, 1951; Anderson and Hasegawa, 1955; de Gennes, 1960). In the framework of tight-binding approximation, the following expression for the spin-dependent hopping resonance integral d_{ij} was obtained (Anderson and Hasegawa, 1955):

$$d_{ij} \approx \varepsilon_\sigma \lambda_\sigma^2 \cos\theta \cos(\varphi/2) \tag{2}$$

where ε_σ is a one-electron energy, λ_σ is the covalent-mixing parameter between e_g orbitals of Mn ions and σ-bonding oxygen p orbitals, $(180^\circ - \theta)$ is the O–Mn–O bond angle, and φ is the angle between the spins of adjacent Mn^{3+} and Mn^{4+} ions. In this formalism, the hopping probability, or in other words bandwidth W, can be increased (the carriers become more itinerant) (i) by decreasing angle θ down to 0, that is, increasing the tolerance factor t up to 1; (ii) by applying external hydrostatic pressure, which increases covalent-mixing parameter λ_σ, that is, reduces Mn–O bond length; and (iii) by means of long-range magnetic ordering for $T < T_C$, which aligns adjacent Mn spins parallel to each other and thus reduces angle φ down to 0. The phase diagram for prototypic $La_{1-x}Ca_xMnO_3$ (Schiffer, Ramirez, Bao and Cheong, 1995), shown in Figure 3, demonstrates complex behavior of different electronic and magnetic phases as a function of doping level, x. Low-doped LMO, being an antiferromagnetic insulator (AFI), transforms into a canted antiferromagnet (CA) for $0 < x < 0.07$, and then to a ferromagnetic insulator (FI) for $0.1 < x < 0.15$. Insulator-to-metal transition occurs at $x = 0.175$ and further for $0.2 < x < 0.45$ ferromagnetic metallic (FMM) phase becomes stable below Curie temperatures, $T_C \approx 170$–250 K. The optimal doping level is found to be around $x = 0.33$, thus yielding maximal $T_C \approx 250$–270 K. With further increasing of Ca doping $0.45 < x < 0.87$ a *charge ordered insulating* (COI) phase appears for $100 < T < 250$ K, which transforms into an AFI at low temperatures. The COI phase first observed by Chen and Cheong for LCMO with $x = 0.5$ (Chen and Cheong, 1996) represents itself the ordering of Mn^{3+} and Mn^{4+} ions in real space in the form of Mn^{3+}/Mn^{4+} stripes with corresponding OO. Therefore, in spite of increased charge density ($x \sim 0.5$), charges are localized within these stripes owing to cooperative JT effect, which is manifested by superstructural ordering of Mn^{3+} O_6 and Mn^{4+} O_6 octahedra as reflected by electron diffraction. The end member of the family, $CaMnO_3$, shows AFI phase of G-type, in which the spin of each Mn^{4+} ion is ordered antiparallel to its six nearest neighbors owing to the antiferromagnetic superexchange Mn–O–Mn interaction (Goodenough, 1955).

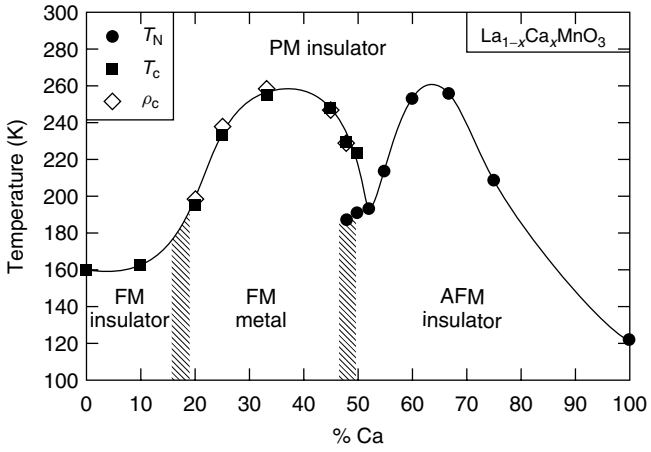

Figure 3. Phase diagram for $La_{1-x}Ca_xMnO_3$. FM: ferromagnetic metal; FI: ferromagnetic insulator; CAF: canted antiferromagnetic; AF: antiferromagnetic insulator; CO: charge ordered insulator. Figure 4. Phase diagram for isovalent substituted manganites $Ln_{0.7}Ae_{0.3}MnO_3$ (Ln = La, Pr; and A = Ca, Sr, Ba) (a) and for $La_{1-x}Sr_xMnO_3$. (Reproduced from W. Archibald *et al*., 1996, with permission from the American Physical Society. © 1996.)

Another phase diagram with data from Hwang *et al*. (1995) and Urushibara *et al*. (1995) is shown in Figure 4 in the form adopted from Archibald, Zhou and Goodenough (1996). It illustrates the influence of lattice effects or internal chemical pressure, quantified by the tolerance factor, t, and average A-site cation radius, $\langle r_A \rangle$. Modification of internal lattice strain can be achieved either by isovalent substitutions on the A site for $Ln_{0.7}Ae_{0.3}MnO_3$ system (see Figure 4a), while keeping doping level constant, or by changing doping level as well, as exemplified for canonic DE system $La_{1-x}Sr_xMnO_3$ (Figure 4b). Maximal Curie temperature, $T_C = 360$ K, and the strongest DE were reported for $La_{0.7}Sr_{0.3}MnO_3$ with $t = 0.98$. Remarkably, LBMO with the largest value $\langle r_A \rangle = 0.1435$ nm and practically cubic structure ($t = 0.998$) has a lower $T_C = 320$ K in disagreement with the DE model. A similar $T_C - \langle r_A \rangle$ phase diagram was reported in Hwang, Palstra, Cheong and Battlog (1995), where the lattice strain was additionally increased by hydrostatic pressure for the same manganites as in Figure 4(b). T_C increases with hydrostatic pressure in accordance with DE predictions. Remarkably, the strongest changes of T_C occurs for $0.96 < t < 0.98$, that is, for the LCMO system, in which the DE contribution is weakened compared to that in LSMO. A competing electron-lattice (EL) interaction (Millis, Littlewood and Shraiman, 1995) due to the JT effect becomes dominant in manganites with small values of $\langle r_A \rangle$, that is, for $t < 0.96$, which show distorted perovskite structure. For example, $Pr_{0.7}Ca_{0.3}MnO_3$ (PCMO) with $t = 0.95$ is no more ferromagnetic, instead a *COI* state becomes stable for $T < T_{CO} \sim 240$ K and transforms into an AFI state at lower temperatures. Thus, the tolerance factor may be viewed as a structural parameter, which reflects a relative strength of the DE and EL interactions (Hwang *et al*., 1995). Perovskite manganites are classified with respect to their bandwidth, W, as *large bandwidth* materials, which are definitely LSMO and LBMO with $t \sim 1$ and DE < EL; *middle bandwidth* (LCMO) $t = 0.97$ and DE ∼ EL; and *small bandwidth* (PCMO) $t = 0.95$ and EL > DE.

2.3 Cation disorder

As we have seen in the previous paragraph, both *bandwidth* and *filling* control are carried out by chemical substitutions on the A sites in the perovskite lattice with corresponding changes of the average ionic radius of the A-site cation, $\langle r_A \rangle$, and the tolerance factor, t. This inevitably leads, in most cases, to the A-site *cation disorde*r because of the different ionic radius of A-site cations.

Rodriguez-Martinez and Attfield (1996) have quantified the disorder in terms of the variance of ionic radii $\sigma^2 = \sum y_i r_i^2 - \langle r_A \rangle^2$ about the mean $\langle r_a \rangle$ (y_i is the fractional occupancy, $\sum y_i = 1$). They performed a systematic study of bulk compounds $R_{0.7}M_{0.3}MnO_3$ (R = La-Sm; and M = Ca, Sr, and Ba) with the same $\langle r_a \rangle = 0.123$ nm but different values of disorder, $\sigma^2 = 0.001 - 0.024$. Surprisingly, they found that Curie temperature, T_C, decreases linearly with increasing σ^2, as shown in Figure 5, from 363 down to 60 K. The samples with very large disorder, $\sigma^2 > 0.015$ Å^2, seem to be not more microscopically homogeneous due to possible segregation of A-site cations, although they look single phased in X-ray powder diffraction. These samples show electronically inhomogeneous behavior, indicated by two maxima on the R(T) curves, and by disparity between T_C and T_{MI} for $\sigma^2 = 0.024$ Å^2. A mixture of antiferromagnetic and ferromagnetic regions for $T > T_C$ was also suggested for 'disordered' samples, based on the observed deviation of the inverse magnetization from the classical Curie–Weiss behavior.

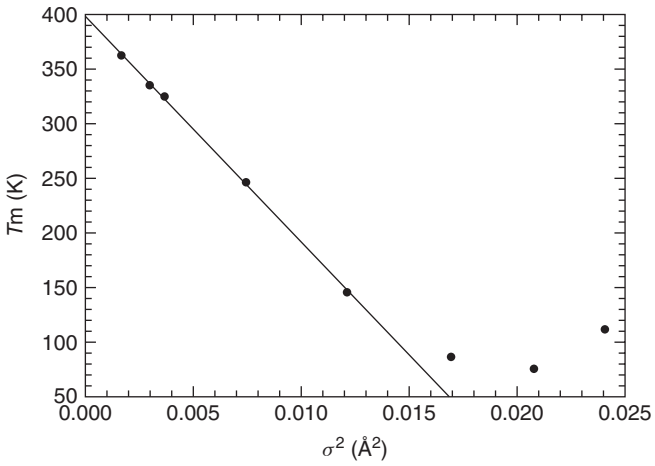

Figure 5. Decrease of the Curie temperature by increasing of the disorder. (Reproduced from L.M. Rodriguez-Martinez *et al*., 1996, with permission from the American Physical Society. © 1996.)

The disorder-induced reduction of T_C was assigned to the size mismatch–induced strain fields with corresponding JT distortions of the MnO_6 octahedra, resulting from oxygen displacements, and shown to obey the following form:

$$T_m = T_m(0) - pQ^2 \tag{3}$$

Here, $T_m(0)$ is the transition temperature for an ideal cubic ($t = 1$) manganite with $r_A{}^0 \approx 1.4$ nm and without cation disorder, $\sigma^2 = 0$. The strain term is proportional to anion displacements $Q = \sigma$ (p is force constant), which are random due to A-site disorder, or can be ordered due to changing of average A-site radius: $Q_0 = r_A{}^0 - \langle r_A \rangle$. The important conclusion was that for relatively small average ionic radii $\langle r_A \rangle < 0.122$ nm the A-site disorder is small and a true variation of T_C with tolerance factor, as shown in Figure 4, can be observed. For large $\langle r_A \rangle >$ 0.123 nm (Ba doping) the A-site disorder dominates, yielding to almost no dependence of T_C on $\langle r_A \rangle$ (see Figure 4). Thus, the A-site disorder seems to be responsible for the lowering of the Curie temperature for LBMO ($T_C = 320$ K), which despite the optimal large $\langle r_a \rangle$ reveals a very large disorder, $\sigma^2 = 0.0131$ Å^2. In comparison, the LSMO with small disorder, $\sigma^2 = 0.0018$ Å^2, shows $T_C = 370$ K. Another important result of Rodriguez-Martinez and Attfield (1996) is that so-called *ideal cubic manganite* without disorder, $\sigma^2 = 0$, would show the highest $T_{MI} \approx 530$ K. The calculations based on the DE model alone give $T_{MI} = 2500$–5000 K (Millis, Littlewood and Shraiman, 1995), whereas those considering the JT distortions of MnO_6 octahedra result in a more realistic value ~500 K (Millis, Littlewood and Shraiman, 1995; Roder, Zang and Bishop, 1996), similar to the estimated T_{MI} without disorder.

The A-site disorder seems to play a key role in the CMR effect. Well-known small bandwidth $Pr_{1-x}Ca_xMnO_3$ (PCMO) has a very small size variance, $\sigma^2 < 10^{-4}$ Å^2, because of close matching of the ionic radii of Pr^{3+} and Ca^{2+}. Remarkably, $Pr_{0.75}Ca_{0.20}Sr_{0.05}MnO_3$ (additional Sr doping is necessary to obtain an insulator-to-metal transition) also with small disorder $\sigma^2 = 1.3 \times 10^{-3}$ Å^2 demonstrates extremely large value of CMR = 10^8% for $T = 85$ K (Raveau, Maignan and Caignaert, 1995). In contrast, other small bandwidth manganites with similar $\langle r_a \rangle$ and T_{MI}, for example, $La_{0.6}Ca_{0.3}Y_{0.1}MnO_3$, but with larger disorder, $\sigma^2 = 2.5 \times 10^{-3}$ Å^2 show only CMR = 4×10^3% at $T = 120$ K (Maignan, Simon, Caignaert and Raveau, 1996).

Recently, the A-site ordered configuration was reported for the so-called *half-doped* manganites, $Ln_1Ba_1Mn_2O_6$ (Arima *et al*., 2002; Akahoshi *et al*., 2003). Owing to specific composition (ratio La/Ba = 1), they form a layered structure, in which both size and charge mismatch can result in A-site ordering. The microstructure of the ordered half-doped manganites, visualized by high-resolution transmission electron microscopy (TEM) and shown in Figure 6, contain the LnO and BaO layers alternately stacked along the c axis with intervening MnO_2 sheets, which thus suffer from no random Coulomb potential. Such an ordering for Ln = Y with small $\langle r_A \rangle = 1.18$ Å was found to stabilize long-range charge/orbital ordered (COO) insulating phase at high temperatures up to $T_{CO} = 500$ K. In contrast, in the disordered LnBMO a random distribution of the Ln and Ba cations between the A positions generates a random Coulomb potential and/or local strain in the MnO_2 sheets. This leads to the collapse of long-range COO insulating phase due to Mn^{3+}/Mn^{4+} frustrations, yielding a spin-glass (SG) state at low temperatures. Remarkably, as shown for disordered $Eu_{0.5}Ba_{0.5}MnO_3$ (Mattheu *et al*., 2004), such an SG state can be responsible for a pronounced CMR effect. Thus, the size mismatch as well as different charge of the constituting A-site cations may strongly influence the phases and the magnetotransport properties in manganites, depending on whether A-site disordered or ordered structure is realized.

2.4 Electronic inhomogeneity of manganites

As we have seen in the previous sections, the spin, charge, and lattice degrees of freedoms compete with one another leading to complex phase diagram of perovskite manganites. However, the complexity of manganites can be even higher – a lot of experimental results (Urushibara *et al*., 1995; Hennion *et al*., 1998; Allodi, De Renzi and Guidi,

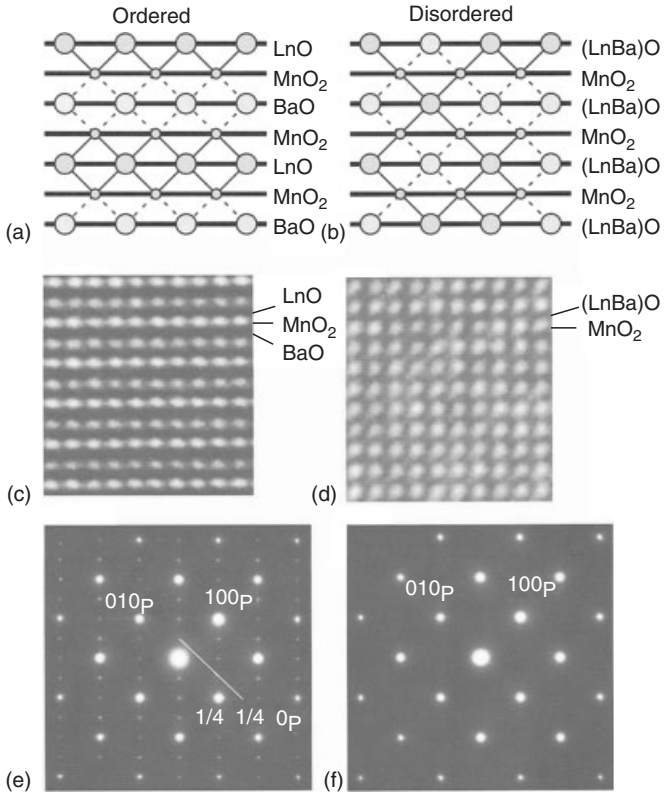

Figure 6. Schematic structure of ordered (a, c, e) and disordered (b, d, f) half-doped manganites $Ln_{0.5}Ba_{0.5}MnO_3$. (Reproduced from D. Akahoshi *et al*., 2003, with permission from the American Physical Society. © 2003.)

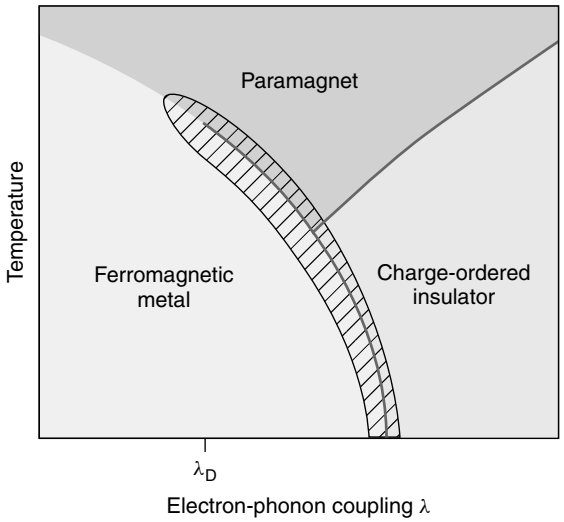

Figure 7. Generic phase diagram as a function of electron-phonon coupling. (Reproduced from N. Mathur *et al*., 2003, with permission from the American Institute of Physics. © 2003.)

1998; de Teresa *et al*., 1997; Linn *et al*., 1996; Fernandez-Baca *et al*., 1998; Mori, Chen and Cheong, 1998) as well as theoretical computational models (Moreo, Yunoki and Dagotto, 1999; Dagotto, Hotta and Moreo, 2001; Moreo *et al*., 2000; Burgy *et al*., 2001; Ahn, Lookman and Bishop, 2004) evidence the coexistence of mixed electronic phases or *electronic inhomogeneity*. In the literature one can also find a term *electronic phase separation* (*EPS*). Actually, a pronounced tendency to EPS has been usually observed for the intermediate (LCMO) and small bandwidth (PCMO) manganites in which FM–DE interaction is weakened in comparison with competing COO. Moreover, for these manganites, the phase transition from para- to ferromagnetic phase was found to be of the first order. In contrast, canonical DE compounds like LSMO and LBMO with second-order phase transition for $T_C = 320–360\,K$ and no signatures for COO (no static JT effect) show no EPS to the best of our knowledge. Thus, it was supposed that electronic inhomogeneity is intimately related to the first-order phase transition whatever the phase coordinate such as temperature, doping level, magnetic field, or hydrostatic pressure is considered. The parameter controlling the EPS tendency seems to be electron-phonon coupling, λ, as summarized in generic phase diagram in Figure 7 (from Mathur and Littlewood, 2003). For $\lambda < \lambda_0$, the lattice effects are small and FM–PM transition is continuous or of the second order; one finds no reasons for mixed phases. There is a critical value λ_0, exceeding of which the transition becomes discontinuous (first order) with discontinuous jump in order parameter and latent heat. Thus, mixed electronic phases were assumed to appear in the vicinity of FM/paramagnetic (PM) or FM/COI phase boundaries as illustrated by the hatched area in Figure 7. Equilibrium coexistence of thermodynamically stable phases at the first-order phase transition is well known to occur owing to disorder or imposed conservation law (Mathur and Littlewood, 2001). The peculiarity of manganites is the quite large scale, compared to the lattice parameter, of the phase coexistence, which can vary from tens to hundreds of nanometers, as well as its sensitivity to quite small external forces.

One of the first direct experimental observations of remarkable electronically inhomogeneous state was the TEM study in LCMO with $x \approx 0.5$ (Mori, Chen and Cheong, 1998), that is, at the border between the FMM/AF-COI phases (see Figure 3). Note that such coexistence contradicts the DE model because charge localization (precursor state to charge ordering) assumes exclusively an AF insulating but not an FMM state. The latter one requires delocalization (hopping) of charge carriers. However, these phases were indeed observed as a mixture between incommensurate charge ordered (CO) and ferromagnetic metallic (FM) charge disordered clusters with a size of 20–30 nm. CO domains consist of paired and unpaired JT distorted Mn^{3+} stripes.

A phase separation (PS) on a much larger submicrometer scale was observed by Uehara, Mori, Chen and Cheong (1999) for $La_{0.625-y}Pr_yCa_{0.325}MnO_3$ system ($y = 0.25–0.4$), in which a CO state is stable for $T < T_{CO} = 210\,K$. The CO AF- and charge-disordered FM domains with characteristic sizes of about 0.3–0.5 μm were revealed by electron microscopy at $T = 17\,K$ in the macroscopically FM state.

A useful local probe technique, scanning tunneling spectroscopy (STS), combined with scanning tunneling microscopy (STM), allows one to study tunneling conductivity, σ, at the surfaces of thin films and single crystals for ultrahigh vacuum conditions. In such experiments, the change of local σ can be observed as a function of temperature as well as magnetic field. We will consider STS/STM observations for thin films in detail in Section 4.

Another group of experiments provide indirect evidences for PS in manganites related to macroscopic effects observed close and far away from phase boundaries in Figure 3. For example, a small angle neutron scattering (SANS) (Hennion *et al*., 1998) and magnetic resonance experiments (Allodi, De Renzi and Guidi, 1998) reported on the FM/AF coexistence in $La_{1-x}Ca_xMnO_3$ bulk samples for $x = 0.05$, 0.08, that is, far away from the MI phase boundary, $x = 0.175$. de Teresa *et al*. (1997) have found short-range FM correlations in LCMO with optimal doping, $x = 0.33$, in the form of small magnetic clusters or *magnetic polarons* with diameter ∼1.2 nm, which exist in the macroscopically PM state for $T > T_C$. Moreover, FM–PM transition according to SANS (Linn *et al*., 1996; Fernandez-Baca *et al*., 1998) has an unconventional character, that is, in contrast to conventional ferromagnet the spin-wave excitations decrease as the temperature approaches T_C from below but a new contribution due to quasielastic spin diffusion grows and then dominates at the transition region. Thus, a two-phase model, FMM with well-defined spectrum of spin waves and PM insulating (spin diffusion), was proposed (Linn *et al*., 1996), in which the fractions of two phases depend on the temperature.

After first experimental observations, some new theoretical computational models appeared, which account for the competition between FM and atomic force microscopy (AFM) phases in the presence of electronic density fluctuations, chemical disorder, and very recently, lattice strain. Within EPS scenario (Moreo, Yunoki and Dagotto, 1999), it was assumed that the observed inhomogeneities are due to different hole densities in competing FM and AFM phases (Figure 2). However, mesoscopic scale coexistence (Uehara, Mori, Chen and Cheong, 1999; Mori, Chen and Cheong, 1998) of electrically charged domains is energetically unfavorable due to a drastic increase of the Coulomb energy. Another model, disorder-induced PS, was also proposed by the Dagotto's group (Dagotto, Hotta and Moreo, 2001; Moreo *et al*., 2000; Burgy *et al*., 2001) to avoid the problems related to Coulomb energy. The model focuses on the first-order transition, for example, FMM/AFI insulator at $x \sim 0.5$, in the presence of A-site cation disorder discussed in the preceding text. Such a transition without disorder is characterized by a discontinuous jump of the order parameter and latent heat over the phase boundary. The stable ground state is then essentially metallic or insulating depending on the location on the phase diagram. Moreo *et al*. (2000) have shown by means of Monte Carlo simulations within 'one'- and 'two'-orbital models that cation disorder, resulting in random distribution of hopping probabilities and exchange interactions, generates mixed phases with coexisting FM and AF domains in the vicinity of the phase transition, which now becomes continuous or percolative. Qualitatively, a phase-separated state can be stable due to two competing opposite tendencies. Firstly, the increase of the interface energy in coexisting FM and AF domains makes PS energetically unfavorable, thus tending to increase the domain size. Secondly, the disorder tends to minimize the size of domains down to the lattice spacing, at which the system can be either the FM or AF according to disorder, fluctuating over the FM/AF phase boundary. As a result, an equilibrium size of PS domains is stabilized. Note that the hole density, for instance, $x \sim 0.5$, is constant and no limitations from the Coulomb energy on the size of competing clusters arise. Thus, even micrometer cluster sizes become possible. Another interesting feature is that the larger the disorder, the smaller the competing AF and FM domains. This seems to be important for understanding the CMR results on Pr-based compounds with small disorder, which assume that very large CMR is compatible with a large size of AF and FM domains.

A recent model (Ahn, Lookman and Bishop, 2004) assumes that strain, instead of electron density or disorder, is a driving force of the PS. The basic assumptions of the new model are (i) without strain (undistorted state) the system is metallic and under strain (distorted state) it is insulating and (ii) there exist coupled short- and long-wavelength lattice distortions of the JT type, which modify elastic energy of the system yielding local (undistorted) and global (distorted) energy minima. Such a 'structural template' governs the formation and topology of the coexisting mixed phases.

3 THIN MANGANITE FILMS

Usually, the preparation of thin films and study of their structure and physical properties are believed to be the topics of applied research. This is mainly because films due to their planar geometry can be easily integrated into different electronic devices. However, as for manganites and likely for other complex oxides, the thin-film aspects become

interesting not only with respect to potential applications, which sometimes even look quite illusive now, but rather for fundamental research. First, because of extreme chemical and structural complexity, even single crystals are not perfect – owing to macroscopic structural defects like twinning and mosaic blocks (Eremenko *et al*., 2001) and corresponding mechanical stress, their electrical and magnetic properties can be far from ideal. Stress-free epitaxial thin films look very attractive because at least along the growth direction due to reduced size their structure is quite perfect. Even more interestingly, thin films with their reduced dimensionality down to nanometer scale provide new boundary conditions and new effects, which cannot be obtained in single crystals. The new branches of fundamental research, nanoscience and nanotechnology, are definitely based on thin-film aspects. Thus, oxide thin-film growth techniques as well as understanding of the processes of film growth become very important.

3.1 Preparation techniques

It is widely accepted that all known oxide thin-film techniques can be subdivided into two large classes: (i) PVD and (ii) chemical deposition techniques. PVD can be realized as a co-evaporation process, that is, when different metals condense on a substrate under ultrahigh vacuum (usually within *molecular-beam epitaxy* technique) with subsequent or simultaneous oxidation. Another possibility is material transfer from the preliminary synthesized target to the substrate realized by means of laser ablation, *pulsed-laser deposition* (*PLD*) or by *magnetron sputtering* techniques. In the following text, we will discuss PLD, because this is a technique that is mostly used for the preparation of complex oxide thin films.

Chemical deposition techniques imply that the desired oxide compound grows as a result of a chemical reaction between the *precursor* compounds (metal-halogenides or metal-organics), that is, chemicals with required metal atoms, bound to a ligand group, containing oxygen, carbon, and hydrogen, usually. The precursors can react being in vapor phase or in a solid phase. The former is the so-called *chemical vapor deposition* (*CVD*), one of which modifications *metalorganic chemical vapor deposition technique* (MOCVD) is a basic industrial technique for the preparation of $A^{III}B^{V}$ semiconductors. The techniques with precursors reacting in solid phase are called *chemical decomposition* routes; they are compatible with spin and deep coating techniques as well as with spray pyrolysis technique. In Section 3.1.2, a chemical deposition route, for example, *metalorganic aerosol deposition* (MAD), combining the principles of MOCVD and technical arrangement of spray pyrolysis, will be discussed in detail.

3.1.1 Pulsed-laser deposition

In Figure 8, a schematic diagram of a typical PLD set up is shown (Krebs *et al*., 2003). Short (few nanoseconds) pulses of high-energy laser radiation (usually KrF laser with wavelength $\lambda = 248$ nm) are focused on the surface of a target, yielding to rapid heating or superheating of all constituting elements up to their evaporation temperature. The removal of the material from the target occurs by means of an explosion mechanism with the resulting plume containing the ions, atomic aggregates as well as liquid droplets. In contrast to thermal evaporation, which yields a vapor composition in accordance with equilibrium vapor pressures of the target elements, the laser-induced expulsion produces a plume of material with stoichiometry similar to the target. This is a decisive advantage of PLD in obtaining complex oxides, containing elements with significantly different evaporation temperatures. Despite the quite clear operation setup, preparation of films by PLD seems to be very complex phenomenon, including different stages such as interaction of laser beam with the target, dynamics of ablated materials, deposition of ablated materials on the substrate, and finally nucleation and growth of a thin film. These processes as well as recently developed modifications of PLD were discussed in detail in the literature (Venkatesan, 1994; Willmott, 2004). Here we note only that stimulated by the discovery of high-T_C superconductivity, PLD technique has been succeeded with Y–Ba–Cu–O films in Dijkkamp *et al*. (1987). The main further developments include the 'off-axis' variant (Holzapfel *et al*., 1992), which has essentially solved the problem of droplets, and later the 'molecular-beam' PLD (DeLeon *et al*., 1998) with realization of controllable layer-by-layer (LL) growth. Thus, PLD has become a basic technique for the preparation of multicomponent oxide films as well as oxide multilayers and superlattices

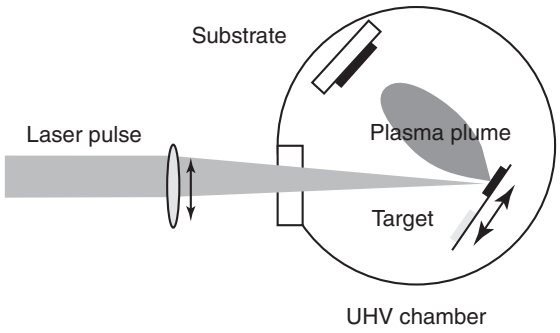

Figure 8. Schematic diagram of a typical PLD setup. (Reproduced from H.-U. Krebs *et al*., 2003, with permission from Springer-Verlag GmbH. © 2003.)

of different functionality. As was already emphasized, first manganite films, showing pronounced CMR effect (von Helmolt *et al*., 1993; Chahara, Ohno, Kasai and Kozono, 1993; McCormack, *et al*., 1994), were also obtained by PLD.

With respect to the growth of high temperature superconductivity (HTSC) as well as of manganite oxide thin films, the oxygen deficiency still remains a problem for PLD or for other PVD techniques using vacuum. As was shown in many papers, the film structure and magnetotransport properties of manganite films are very sensitive to oxygen deficiency, which may result due to insufficient oxygen partial pressure (usually 1 mbar) during deposition. Preparation of oxide films at higher oxygen partial pressures within a vacuum technique seems to be quite sophisticated. In this sense, *chemical deposition* routes compatible with up to 1 bar oxygen pressure look more appropriate.

3.1.2 Metalorganic aerosol deposition (MAD)

Thin manganite films can be grown by means of unconventional MAD technique (Moshnyaga *et al*., 1999). MAD is a chemical route, originally developed for the preparation of HTSC $YBa_2Cu_3O_{7-x}$ films (Khoroshun *et al*., 1990) and also used for other oxide films of different functionality (Ivashchenco *et al*., 1995; Kuliuk *et al*., 1995; Moshnyaga *et al*., 1997). Similar to other chemical deposition techniques (CVD, MOCVD) to obtain an oxide film within MAD, one should be able to carry out the following pyrolysis reaction:

$$\mathrm{Me(C_3H_5O_2)}_x + \mathrm{O_2} \xrightarrow{T\,^\circ\mathrm{C}} \mathrm{MeO}_{x/2} + y\mathrm{CO_2}\uparrow + z\mathrm{H_2O}\uparrow \tag{4}$$

Here, $\mathrm{Me(C_3H_5O_2)}_x$ is an organometallic precursor, Me(acetylacetonate) (Me = La, Ca, or Mn), which decomposes under heating or electron beam or UV radiation with the formation of a metal oxide compound in an oxygen containing media. Two types of chemical reactions are important for applications: (i) *homogeneous* pyrolysis, which occurs in a gas phase, is used for the preparation of oxide nanoparticles (Konrad *et al*., 1999) and (ii) *heterogeneous* pyrolysis, which takes place at the interface between gas and a solid, is suitable for growth of thin films. CVD and MOCVD techniques require volatile precursors, large quantities of which can be congruently vaporized at relatively low temperatures (20–100 °C). Sol–gel and spray pyrolysis both use the nonvolatile precursors, which react being in solid state. The MAD technique uses *β-diketonates* of metal chelates as precursors, which have low decomposition temperature $\sim$ 250–300 °C and usually low volatility or even are thought to be nonvolatile (precursors for rare-earth elements). Very fine droplets (aerosols) of a few micrometer sizes allow one to perform the so-called *flash* or fast evaporation (Wahl, Stadel, Gorbenko and Kaul, 2000), which is advantageous for precursors with low volatility. The decomposition/vaporization of aerosols occurs on the heated substrate, thus preventing gas-phase reaction and possible contamination of the growing film with nanoparticles.

The scheme of the MAD is shown in Figure 9. The mixture of organometallic precursors, typically acetylacetonates of the corresponding metals, has been dissolved in an organic solvent. The precursor solution in the form of aerosols with diameter of about 10–20 μm, obtained by a pneumatic nozzle, was transferred onto heated substrate by a carrier gas (compressed air or oxygen). Aerosol flow rate was controlled in the range $v = 0.05$–$10\,\mathrm{mL\,min^{-1}}$ by measuring diffusion light scattering on the droplets. The substrate temperature can be controlled in the region $T_S = 400$–$1000\,^\circ\mathrm{C}$ by detecting the radiation emitted from the substrate heater, using a photodiode optically coupled to the heater by a fiber-optic waveguide. Deposition rate can be varied in the range $v = 5$–$300\,\mathrm{nm\,min^{-1}}$ by changing the concentration of the precursor solution and aerosol flow rate. MAD, compared with other techniques, possesses several advantages: (i) precise control of the film composition, (ii) no vacuum and gas transport lines, (iii) high deposition rates, and (iv) high oxygen partial pressure up to 10^5 Pa.

3.2 Thin-film effects

3.2.1 Growth mechanisms

There are two well-known basic growth modes of thin films: (i) LL growth, also named by Frank and van der Merwe (1949), which takes place when the atoms of growing film

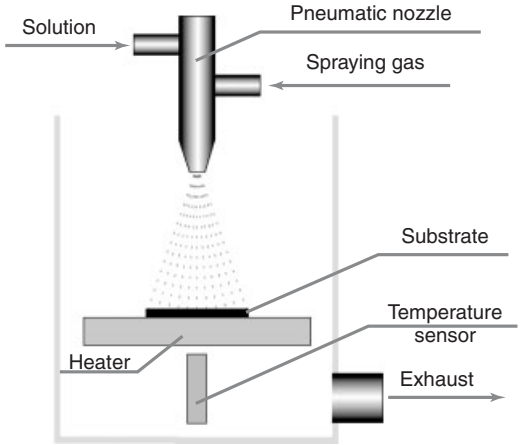

Figure 9. The scheme of the MAD process. (Reproduced from V. Moshnyaga *et al*., 2005, with permission from Springer-Verlag GmbH. © 2005.)

bound preferentially to the substrate surface as to each other promoted by fast diffusion as well; and (ii) 3D island nucleation (Volmer and Weber, 1926), which takes place when the adatoms bound more to each other than to the substrate, favored by slow diffusion. Quantitatively, these two cases can be described within the Young's equation (Lüth, 2001):

$$\gamma_{SV} = \gamma_{SF} + \gamma_{FV} \cos\theta \tag{5}$$

Here γ_{sv}, γ_{sf}, and γ_{fv} are interface energies between substrate (s) and vacuum (v), substrate/film (f) and film/vacuum, respectively. θ is the contact angle between the nucleus and the substrate (see Figure 10). LL growth take place if $\theta = 0$ or undefined, which requires $\gamma_{SV} \geq \gamma_{SF} + \gamma_{FV}$, whereas 3D growth occurs when $0 < \cos\theta < 1$ and thus $\gamma_{SV} \leq \gamma_{SF} + \gamma_{FV}$. Energetically, this means that in the case of LL growth the energy gain (γ_{sv}) due to coating of a substrate by a film exceeds the energy cost ($\gamma_{sf} + \gamma_{fv}$) related with the formation of new interfaces; the film 'wets' the substrate completely. In contrast, for 3D growth the growing film tries to minimize the interface energy, γ_{sf}, and its own surface energy, γ_{fv}, thus 'balling up' on the substrate. Actually, due to condensation of a film from a supersaturated vapor phase, there is an additional energy gain proportional to the Gibbs's free enthalpy per unit volume $G_V = k_B T \ln(p_0/p)$ ($k_B T$ is thermal energy, p and p_0 are partial pressures in the supersaturated vapor phase and equilibrium pressure for the film material for given substrate temperature T) (Willmott, 2004). The supersaturation degree, $S = p_0/p$, is an important parameter, which describes how far away from equilibrium the process of film growth is. S values can be significantly different for various deposition techniques. For example, the PLD technique can be viewed as essentially nonequilibrium – the plasma nature of ablated material plume leads to extreme high supersaturation, $S \sim 10^9$, yielding very high fractional density of stable nucleating sites $N_S = 0.6$ (Willmott, 2004). The rate of nucleation (growth rate) is proportional to N_S as well as to the rate of impingement, therefore the high supersaturation in turn results in films composed of large amount of small crystallites similar to rapid thermal deposition at low temperatures. The PLD technique operates close to this regime (Krebs, Bremert, Störmer and Luo, 1995). For comparison within molecular-beam epitaxy, the growth of films can be close to thermal equilibrium ($S \sim 10^4$ and $N_S \sim 5 \times 10^{-4}$), resulting in perfect large crystal domains (Tersoff, Johnson and Orr, 1997). Thus, growth conditions close to equilibrium, that is, low supersaturation and impingement rate as well as high diffusion rate would inhibit nucleation tendency, that is, 3D growth and would promote LL growth with atomically smooth and large terraces. As for complex oxides like manganites with perovskite crystalline structure, the preparation of LL films is intimately coupled to heteroepitaxial growth on the appropriate single crystalline oxide substrates.

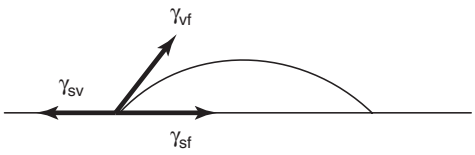

Figure 10. Nucleation site of a film on the substrate.

3.2.2 Epitaxial growth, misfit stress

Preparation of atomically smooth manganite films with perfect crystalline structure is a challenging task not only for the better understanding of intrinsic magnetotransport phenomena but also for the so-called *interface engineering* (Yamada *et al.*, 2004). The latter was recently shown to be extremely important both for low-field TMR in LSMO/$SrTiO_3$ (STO)/LSMO structures (Kwon *et al.*, 1997) as well as for architecting and growth of novel synthetic magnetic (Ogawa *et al.*, 2003) and ferroelectric (FE) materials (Haeni *et al.*, 2004). In many earlier reports, epitaxial manganite thin films can be successively grown using deposition techniques as discussed in Section 3.1 on single crystalline standard substrates like STO, $LaAlO_3$ (LAO) and $NdGaO_3$ (NGO), which have similar perovskite structure. Less used were the substrates of cubic MgO or ZrO_2:Y (YSZ).

In Figure 11, we present an example of heteroepitaxy of LSMO film on STO substrate, obtained by PLD technique (Izumi *et al.*, 1998) within LL-growth mode, controlled by reflection of high-energy electron diffraction (RHEED). Oscillations of specular spot in RHEED patterns as a function of deposition time with a period corresponding to one unit cell clearly demonstrate LL growth. The surface of the film studied by AFM was extremely smooth and flat – one can evidently see flat terraces of about 100 nm width and steps of 0.4 nm height. The alignment and spacing between steps were found to be the same as those of the STO substrate. By means of coaxial impact collision ion scattering technique (CAICISS) (Kawasaki *et al.*, 1994), it was observed that the top atomic layer is MnO_2. Thus LSMO film is considered to be an alternative stack of (La,Sr)O and MnO_2 atomic layers along the [001] direction. The in- and out-of-plane lattice parameters of the LSMO/STO film were found to be significantly different, $a = 0.391$ nm and $c = 0.383$ nm, indicating that film structure changes from the rhombohedral (see Section 1) with pseudocubic lattice constant $a = 0.387$ nm (see Section 1) to a tetragonal, $a \approx b > c$. The reason is *epitaxy misfit stress*, $\varepsilon = (a_{STO} - a_{LSMO})/a_{STO} \sim 0.9\%$, which being relatively small prevents the formation of misfit dislocations at the interface and results in coherently strained

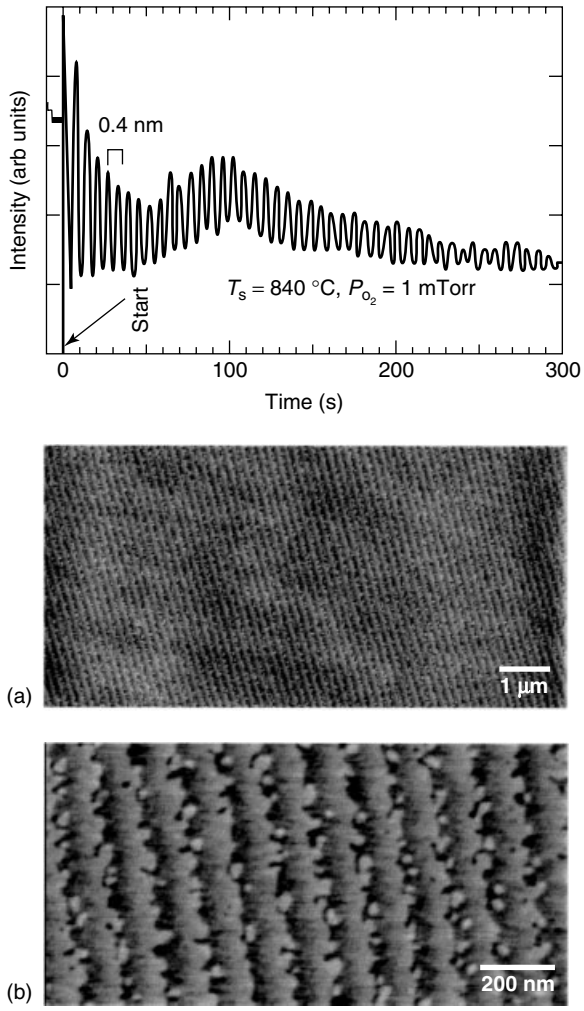

Figure 11. Layer-by-layer grown $La_{0.6}Sr_{0.4}MnO_3$ film. (Reproduced from Izumi *et al.*, 1998, with permission from the American Institute of Physics. © 1998.)

atomic planes. The strain has biaxial nature, that is, the film is tensile strained in (a, b) plane, that is, $a_{\text{film}} > a_{\text{bulk}}$ and compressively strained along the [001] direction, $a_{\text{film}} < a_{\text{bulk}}$, yielding tetragonal large lattice distortion in the film. Surprisingly, the strain persists up to the thickness of about 100 nm and leads to the significant change of the bulk film properties: (i) Curie temperature $T_C = 310$ K instead of 370 K seen in the bulk and (ii) the resistance of the films was about 1 order of magnitude larger than that for single crystal.

Substrate-induced lattice strain effects in thin manganite films were studied in a number of papers (Gommert, Cerva, Wecker and Samwer, 1999; Wang *et al.*, 2000; Bibes *et al.*, 2001; Wiedenhorst *et al.*, 1999; Lebedev *et al.*, 1998; Rao *et al.*, 1998, 1999) by means of changing the substrate nature and film thickness. Usually, the substrates of STO ($a = 0.3905$ nm), resulting in tensile in-plane stress, and LAO ($a = 0.3793$ nm), yielding a compressive in-plane stress, were used. The dependence of lattice strain in epitaxial $La_{0.8}Ca_{0.2}MnO_3$ films as a function of their thickness is shown in Figure 12 both, for films grown on STO and LAO substrates (Rao *et al.*, 1998, 1999). A clear difference between STO and LAO can be seen, namely, the LCMO/STO films are coherently strained up to the thickness of about 100 nm. In contrast, the LCMO/LAO films do not overtake the in-plane lattice constant of the substrate, that is, they are not coherently strained even down to 2–5 nm. This was ascribed to a very large lattice misfit between LCMO and LAO, $\varepsilon = 2.7\%$, which cannot be elastically accommodated, thus resulting in interface dislocations and stress relaxation. Moreover, as was also shown (Rao *et al.*, 1998, 1999; Biswas *et al.*, 2000), stress relaxation under large lattice misfit yields 3D- rather than LL-growth mode.

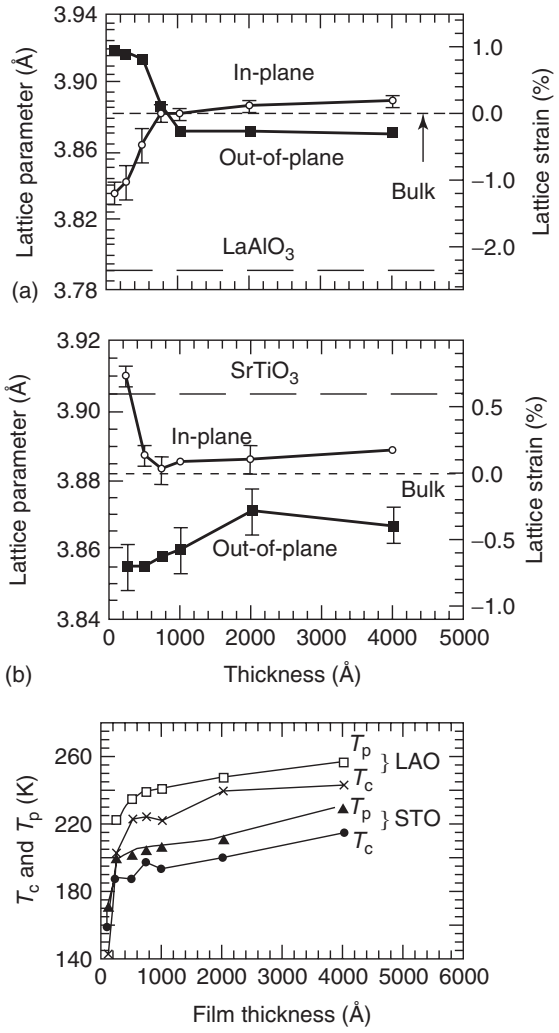

Figure 12. Stress effect induced by substrate-film lattice misfit. (Reproduced from Rao *et al.*, 1999, with permission from the American Institute of Physics. © 1999.)

As is shown in Figure 12(b), the MI transition at T_p as well as Curie temperature, T_C, are extremely sensitive to the lattice strain and decrease about 80–100 K. Millis, Darling and Migliori (1998) quantified the lattice strain effect on T_C due to both bulk strain, ε_b, and JT stress, ε_{JT}, which acts as tetragonal distortion. The obtained dependence of T_C on the lattice strain is described by equation (3):

$$T_C(\varepsilon) = T_C(0)(1 - \alpha\varepsilon_b - 1/2\Delta\varepsilon^{*2}) \quad (6)$$

Here $\alpha = 1/T_C(dT_C/d\varepsilon_b)$ and $\Delta = 1/T_C(d^2T_C/d\varepsilon^{*2})$ are the strain coefficients for bulk and JT strain respectively. The second, symmetry conserving, term in equation (4) describes the change of kinetic energy as a function of strain, which can be either positive due to compressive strain or negative (tensile) leading to increasing or decreasing of T_C, respectively. The bulk strain can be naturally assigned to the change of Mn–O distances as a result of applying pressure. The third, symmetry braking, term relates to the electron localization due to splitting of e_g states of Mn ions caused by static JT effect (see Section 1); the Mn–O–Mn bond angle is corresponding structural parameter, which changes due to JT strain (Radaelli *et al.*, 1997). Being in qualitative agreement with experimental results, the model lacks in detailed description because the strain effects were found to be accompanied with increasing disorder (Aarts, Freisem, Hendrikx and Zandbergen, 1998). This is because the change of film volume due to epitaxy (contraction or expansion) can be stabilized also by the formation of defects like oxygen deficiency (Sun *et al.*, 2000) or partial cation substitution (Rao *et al.*, 1997). Summarizing, the stress-induced effects usually lead to degradation of magnetic and electric properties of manganite films. Hence, preparation of strain-free manganite films on appropriate substrates becomes extremely important problem.

Single crystalline perovskite NGO with (110) orientation possesses lattice constant $a = 0.386$ nm, which is very close to lattice parameter of manganite films, $a = 0.387$ nm; the lattice misfit is only about 0.2%. Recently, (Mitra *et al.*, 2005) have demonstrated LL growth of strain-free LCMO films on NGO substrates by PLD technique. The morphology of the films studied by STM shows large terraces of about 360 nm width and mean square roughness, $RMS = 0.03$ nm. High MI transition temperature $T_P \approx T_C = 268$ K accompanied by very sharp transition were observed. Earlier (Gommert, Cerva, Wecker and Samwer, 1999), a potential of cubic MgO substrates ($a = 0.421$ nm) for the preparation of high quality manganite films by PLD was shown. In this case the lattice misfit is extremely large, $\epsilon = 8\%$, and misfit dislocations, indeed, were present in a 2 nm thick interface region with enhanced disorder but then after the film was almost defect free showing magnetization close to the bulk LCMO. Using MAD technique, we have demonstrated a possibility to grow LL LCMO films on MgO substrate (Moshnyaga, 2005). Typical surface morphology image, obtained by STM, is shown in Figure 13. The film is very smooth, $RMS = 0.1$ nm, and contains large terraces of 100–200 nm, divided by one unite cell steps of ∼0.4 nm height. Interestingly, the LCMO/MgO interface looks quite different from that in Gommert, Cerva, Wecker and Samwer (1999) – it is sharp and smooth with only two to three distorted atomic layers of LCMO. Remarkably, misfit dislocations are present, but located almost exactly on the film-substrate interface, causing an effective mechanism of misfit stress accommodation already in the first atomic layers of growing LCMO film.

3.2.3 Grain boundaries and interfaces

In early studies of manganites, it was already shown that despite intrinsic magnetotransport, related to MI transition

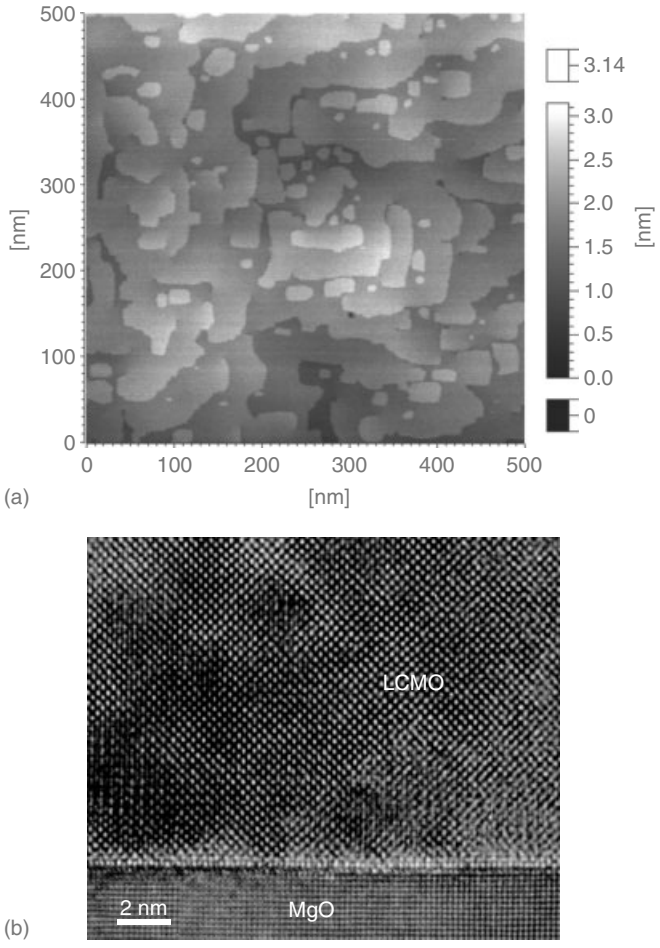

Figure 13. (a) Surface morphology and (b) HREM image (Courtesy of O. Lebedev, EMAT RUCA, University of Antwerp.) of the film interface of a layer-by-layer LCMO/MgO(100) film grown by MAD technique.

and CMR, extrinsic effects like TMR (Hwang, Cheong, Ong and Battlog, 1996) due to static disorder on the interfaces like Grain boundaries (GB) look interesting for low-field applications. Another important feature is that manganites can be viewed as half-metallic compounds (Park *et al*., 1998) with almost fully spin polarized charge carriers on the Fermi level for $T < T_C$. This causes the importance of manganites for *spin electronics*, which along with charge of electron takes into account also the spin degree of freedom, thus dealing with spin-dependent electron transport. In the following text, we discuss the structure and properties of artificially made interfaces.

GB in bulk materials are of limited interest because it is very difficult to control them. To obtain controllable GB in thin films, the bicrystal substrates, usually of STO, were used (Gupta *et al*., 1996; Steenbeck *et al*., 1998; Phillip *et al*., 2000). Such substrates are composed of two misoriented crystalline blocks, thus forming one well-defined wide angle GB. The misorientation angle can be varied usually in the range 8–36°. A manganite film then grows epitaxially on these crystalline blocks, resulting in a well-defined one GB in the film as schematically shown in Figure 14(a). The local structure of grain boundary (Gross *et al*., 2000), visualized by high-resolution electron microscopy (HREM), is shown in Figure 14(b). The GB interface in the film looks as a straight line and is composed of about few nanometer-wide structurally distorted region likely due to accumulation of misfit dislocations and/or nonstoichiometry defects. Moreover, charge carrier concentration in the GB region can be also reduced due to band bending effects similar to that known for high-T_C superconductors (Chisholm and Penneycook, 1991). Hammerl *et al*. (2000) have demonstrated that the GB in Y–Ba–Cu–O films can be additionally doped with Ca to compensate the depletion of charge carrier concentration and thus to increase critical current density.

Another way to design TMR elements is to create interfaces containing manganite/insulator/manganite layers. The in-plane heterostructures with insulating STO layer grown by PLD technique were used for magnetic tunnel junctions (Lu *et al*., 1996; Sun *et al*., 1996; Luo and Samwer, 2001; Pailloux *et al*., 2002; Bowen *et al*., 2003). An example of such trilayer heterostructure is reproduced in Figure 15; it demonstrates sharp and coherent LSMO/STO/LSMO interfaces. No indications on the appearance of misfit dislocations were observed. Köster *et al*. (2002) have shown a possibility to obtain vertical LSMO/MgO/LSMO interfaces by means of self-assembled simultaneous growth of nanocomposite (nanocolumnar) in $(LSMO)_{1-x}$:$(MgO)_x$ on sapphire substrates by MAD technique. The films exhibit pronounced TMR at low temperatures due to MgO insulating layer working as a vertical tunneling barrier. In Figure 15 (b) one can see two types of 45°-misoriented

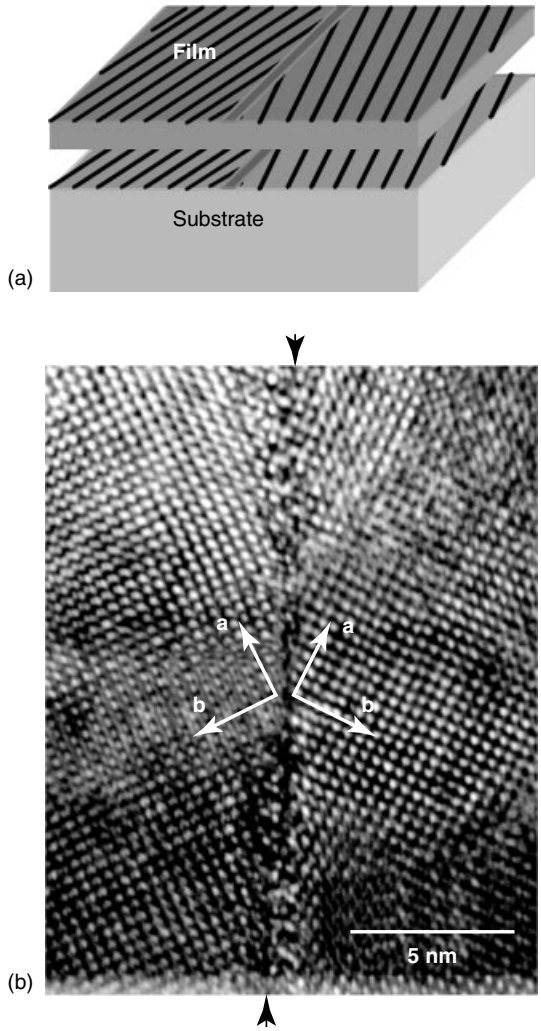

Figure 14. (a) Schematic view of a film epitaxially grown on bicrystal substrate. (b). HREM image of grain boundary region. (Reproduced from Gross *et al*., 2000, with permission from Elsevier. © 2000.)

interfaces: (a) undoped LSMO/LSMO interfaces which show no TMR and are similar to epitaxial films and (b) 'doped' of 'filled' LSMO/MgO/LSMO interfaces, composed of crystalline LSMO domains, separated by MgO layer. The latter interfaces build a network of vertical tunneling barriers. Very recently (Esseling *et al*., 2005), the vertical LSMO/MgO/LSMO interfaces were characterized with respect to (1/f)-noise, which is a well-known limiting factor for device applications. The noise level characterized by a dimensionless parameter, $\langle a_V \rangle \sim 10^{-27}\,m^3$, was found to be comparable with the noise from epitaxial films: strained film on STO has $\langle a_V \rangle \sim 10^{-24}\,m^3$ and unstrained grown on NGO substrate possess $\langle a_V \rangle \sim 10^{-30}\,m^3$ (Reutler *et al*., 2000). These data confirm high quality of LSMO/MgO/LSMO

interfaces, prepared by self-assembled growth within MAD technique.

4 MAGNETORESISTANCE EFFECTS IN MANGANITE FILMS

4.1 Metal–insulator transition and colossal magnetoresistance

4.1.1 General comments

As was mentioned in Section 2 continuous and broad interest to the perovskite manganites is basically caused by the fact that they show MI transition and CMR effect. To illustrate the interrelations between different phase transitions, in Figure 16 we present temperature dependence of the resistance (a), magnetization (b), and CMR (c) for an epitaxial LCMO/MgO film, grown by MAD technique. One can see that for $T > T_{\mathrm{MI}}{\sim}270\,\mathrm{K}$, the film shows insulating-like behavior in the sense that $\mathrm{d}\rho/\mathrm{d}T < 0$, which changes to a metallic-like dependence with $\mathrm{d}\rho/\mathrm{d}T > 0$ for $T < T_{\mathrm{MI}}$. Very close to the preceding transition is the Curie temperature, $T_{\mathrm{C}} = 263\,\mathrm{K}$, defined as the temperature of the minimum of the function $(1/M)(\mathrm{d}M/\mathrm{d}T)$, where M is the film magnetization (Rajeswari *et al*., 1998). Apparently, CMR is very large only in a narrow region in the vicinity of T_{C}, or in other words, large CMR is coupled to the highest level of magnetic disorder (Ashckroft and Mermin, 1981), which is very sensitive to applied magnetic field as well as other factors like temperature, hydrostatic pressure, or even electromagnetic radiation. For completely ferromagnetically ordered material, for $T < T_{\mathrm{C}}$ as well as for noncorrelating (disordered) PM spins ($T \gg T_{\mathrm{C}}$) CMR is negligibly small.

Basically, the CMR phenomenology is in accordance with DE model (Zener, 1951; Anderson and Hasegawa, 1955; de Gennes, 1960). See Section 2 for the large bandwidth manganites like LSMO, showing highest $T_{\mathrm{C}} \sim 370\,\mathrm{K}$, second-order para-ferromagnetic phase transition (Mira *et al*., 1999) and metallic-like behavior also in PM phase. For middle bandwidth manganites like LCMO with moderate $T_{\mathrm{C}} \sim 260\,\mathrm{K}$ and first-order MI phase transition as was first suggested by Millis, Darling and Migliori (1998), the larger resistance as well as an insulating-like behavior in PM phase cannot be explained within the DE model. An additional EL interaction due to JT effect should be taken into account.

The charge localization (see Section 2.1) occurs by means of static or dynamic JT distortions of MnO_6 octahedra resulting in the formation of lattice *polarons* for $T > T_C$, that is, localized carriers tightly bound to the local lattice deformation (Billinge *et al*., 1996; Kim *et al*., 1996; Jaime *et al*., 1997). Such a carrier with corresponding local distortion can move through the lattice by means of a temperature activated hopping mechanism (Mott, 1990) with insulating-like temperature dependence of the resistivity, $\rho \sim \exp(T_0/T)^{1/4}$ (Viret, Ranno and Coey, 1997). Moreover, PM state shows the *correlated lattice distortions* observed by small angle neutron (SANS) and X-ray scattering techniques (Dai *et al*., 2000; Adams *et al*., 2000; Kiryukhin *et al*., 2003). The correlation length was found to be of several lattice constants, varying in the range 1.2–2.8 nm for LCMO with different doping level (Dai *et al*., 2000). Remarkably the scattering intensity, proportional to the concentration of these nanoscaled correlated regions, increases approaching T_C and can be suppressed by applied magnetic field (Koo *et al*., 2001), thus mimicking temperature dependence of the resistivity and CMR effect. Furthermore (Kiryukhin *et al*., 2003), it was shown that correlated polarons are compatible with orthorhombic structure but not with the rhombohedral one. Figure 17 illustrates the temperature behavior of the nanoscaled structural correlations in the $La_{0.75}(Ca_{0.45}Sr_{0.55})_{0.25}MnO_3$ system, for which (P_{nma}/R-3c) structural phase transition occurs for $T_0 = 370$ K. One can see that polaron correlations are suppressed both for $T < T_C$ due to the increase of DE in FM phase and for $T > T_0$ in PM state within the rhombohedral structure. The latter, being a more symmetric pseudocubic structure with three equivalent crystallographic axes, seems to be incompatible with the existence of long-range strain fields in nanoscaled regions with static JT effect.

Summarizing, one can view correlated polarons in the form of nanoscaled structural correlations as a precursor state for the long-range COO state, which builds up when DE contribution is progressively suppressed by means of bandwidth or filling controls. By enhancing delocalizing tendencies due to DE in an optimally doped materials for $T < T_C$, the correlated polaron regions will 'melt' at the expense of metallic regions, characterized by conventional spin-wave excitations rather than by diffusive inelastic contribution from correlated polarons, both detected by SANS (Linn *et al*., 1996; Fernandez-Baca *et al*., 1998). Metallic phase can be also treated as charge and orbitally disordered. Thus, competing DE and electron–lattice interactions may result in an electronically inhomogeneous ground state with coexisting domains of FMM and AFI phases. On the basis of effective medium approach, Jaime *et al*. (1999) proposed a two-phase model with magnetic field and temperature dependent concentration of metallic regions, embedded in a polaronic background, having an activated electrical conductivity.

4.1.2 Phase separation studied by local probe techniques

To study the phase coexistence in manganites, the local probe techniques like STM coupled to STS were used (Fäth *et al*., 1999; Becker *et al*., 2002; Renner *et al*., 2002; Chen *et al*., 2003; Moshnyaga *et al*., 2006). These techniques allow one not only to visualize the surface morphology of a manganite thin film or single crystalline sample under ultrahigh vacuum (UHV) conditions but also by measuring the $I-V$ characteristics, to obtain the information on the local surface electronic structure with very high spatial resolution. Owing to modern developments of the STM, such measurements can be performed additionally by varying temperature and magnetic field. Fäth *et al*. (1999) have done the first STS study on the single crystals of $La_{1-x}Ca_xMnO_3$ ($x = 0.25$ and 0.3) as well as on epitaxial LCMO film grown on STO substrate. STS on the LCMO film was measured both for $T < T_C$ and $T > T_C$; unfortunately the temperatures were not specified. For all temperatures the ($I-V$) curves were found to be essentially nonlinear in the range of voltages $V = 0$–4 V. Even for small voltages, one can hardly see linear behavior. However, there was observed a correlation between measurements of four-probe bulk resistivity and tunneling resistivity. Namely, for $T < T_C$, that is, in macroscopically FM and metallic state, the film shows relatively high values of differential

tunneling conductivity $\mathrm{d}I/\mathrm{d}V_{V=0} \sim 1$ ns, which were thus assigned to be 'metallic' (M). In contrast, a low conductivity, $\mathrm{d}I/\mathrm{d}V_{\mathrm{V}=0} \sim 10^{-2}$–$10^{-3}$ ns, measured for $T > T_{\mathrm{C}}$ in the macroscopically PM and insulating state were assigned to be 'insulating' (I). In Figure 18 the distribution of the tunneling conductance $\sigma = \mathrm{d}I/\mathrm{d}V$ taken at 3 V on LCMO/STO film from Fäth *et al*. (1999) is shown for temperature close but lower than T_{C}. One can see that σ is inhomogeneously distributed over the measured area ($500 \times 500\,\mathrm{nm}^2$), containing more conducting regions, colored on the 'red' to 'black' color scale, and less conducting regions ('yellow' to 'white'), both having a cloudlike shape. Characteristic sizes of these electronic structures vary within several tens of nanometers. By applying magnetic field, the average conductivity increases at least for fields close to 9 T (one can see that the conductivity map becomes darker). This behavior is in qualitative agreement with the bulk CMR effect and DE model (Zener, 1951; Anderson and Hasegawa, 1955; de Gennes, 1960), assuming the decrease of electrical resistance in magnetic field due to suppression of magnetic disorder and increase of one-electronic bandwidth (see equation (2). However, locally, σ still remains inhomogeneous in contradiction with DE even at 9 T. A remarkable feature, which was not discussed by Fäth *et al*. (1999), is that magnetic field does not necessary lead to the increase of local σ. Indeed, in some regions (follow, for instance, the 'red' central part at $B = 0$ in Figure 18), one can evidently see that σ decreases (the color changes from red to yellow) with increasing field. Very similar behavior

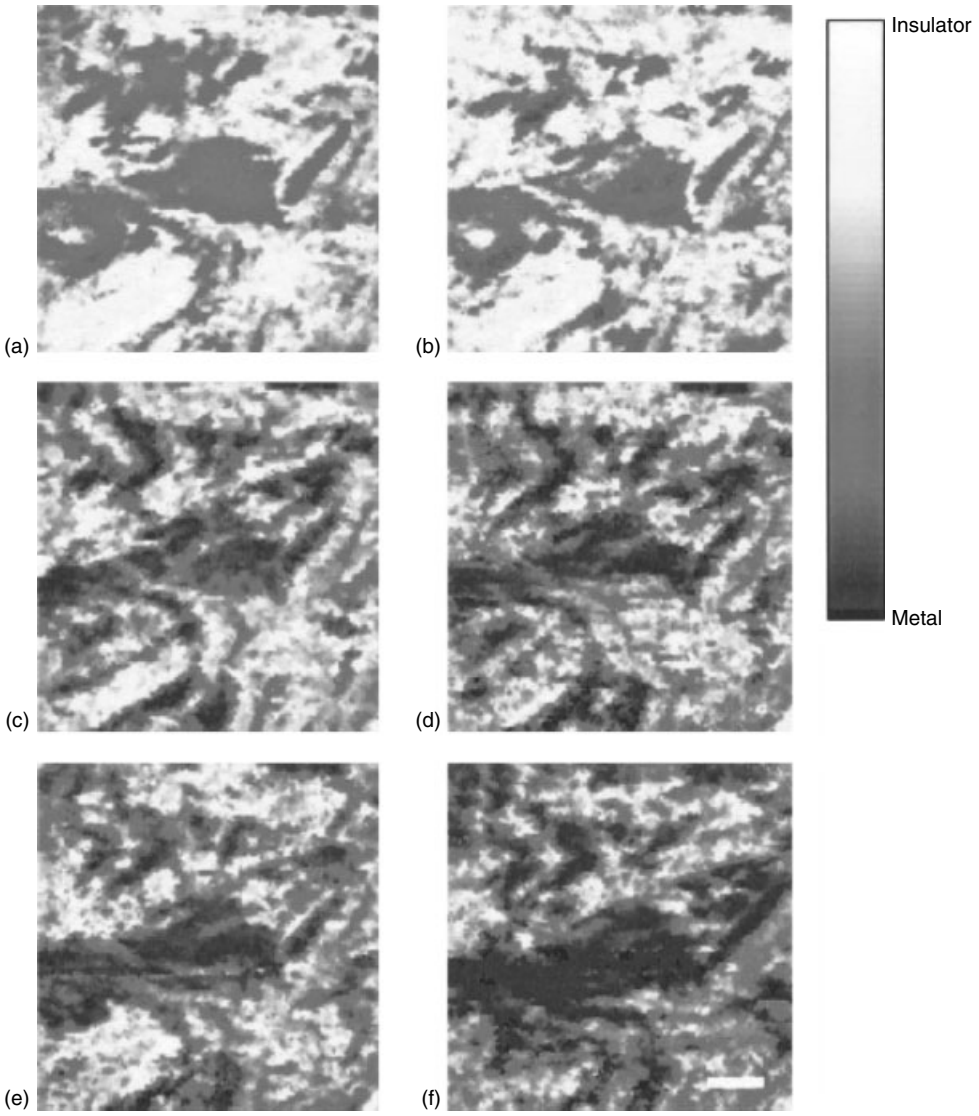

Figure 18. Conductivity maps at 3 V bias for LCMO thin film for magnetic fields of 0, 0.3, 1, 3, 5, and 9 T (a–e). The color represents the slope of the local (I–V) curve at a bias of 3V. (Reproduced from M. Fäth *et al*., 1999, with permission from Science AAAS. © 1999.)

was also seen by Chen *et al*. (2003). Moreover, they have observed that after the field was scanned from 0–5 T and back to 0, the tunneling conductivity map was looking significantly different from the initial STS map, taken before the application of magnetic field. This clearly indicates that field-induced changes in tunneling conductivity are irreversible. Thus, nonmonotonous local $\sigma(H)$ behavior, if considered on a scale 50–100 nm, which is comparable to the size of cloud-like features in Figure 18, may be in disagreement with bulk CMR-like behavior, assuming decrease of the resistance in applied field, and DE model as well. One can rather say that external magnetic field induces rearrangement of metallic and insulating regions. This, likely, indicates that M and I phases are not free – they are coupled together leading to a peculiar magnetic field behavior.

Becker *et al*. (2002) have studied local tunneling conductivity, taken however at $V = 0$, for different temperatures for LSMO and LCMO films. STS images, qualitatively similar to those from Fäth *et al*. (1999) and Chen *et al*. (2003), with coexisting M and I regions were obtained. Moreover, the evaluated concentration of metallic phase was found to be temperature dependent similar to temperature dependence of the bulk material. This confirms similarity between the bulk and surface measurements and rules out a possible 'surface' nature of the observed PS in thin films and single crystals. Renner *et al*. (2002) have obtained STS with atomic resolution on $Bi_{0.24}Ca_{0.76}MnO_3$ single crystal, which behaves as CO insulator for $T < T_{CO}{\sim}240$ K and orders antiferromagnetically at low temperatures. Remarkably, they also observed a coexistence of metallic and insulating domains, which occurs at room temperature, that is, higher than T_{CO}. Owing to success in atomic resolution, a structural characterization of both metallic and insulating phases have been done. The M-phase was found to be cubic with O–Mn–O angle close to 180°, whereas the I phase was orthorhombic showing a 'zig-zag' type structural distortion of Mn–O bonds. Very sharp M/I phase boundary was observed. Thus, as could be expected from structural consideration discussed in Section 1, the manifestation of metallicity is directly related to a more symmetric cubic (or rhombohedral R-3c) structure, while the insulating behavior is caused by lattice distortions within less symmetric orthorhombic P_{nma} structure due to JT effect.

These results make a quantitative basis to discuss other local STS studies, which could be more or less related to extrinsic PS in thin films. Biswas *et al*. (2000) have seen inhomogeneous electronic behavior caused by incomplete strain relaxation in LCMO/LAO films grown according to 3D growth mode. They found an insulating-like tunneling conductivity near the edges of crystalline grains, whereas the central part of the grain was metallic. Bibes *et al*. (2001) observed nanoscale PS on LCMO/STO interfaces and interpreted it within a stress-induced PS due to coherently strained LCMO on the interface. These data seem to be important for the experiments on TMR (see Section 4.2) because stress-induced PS, accompanied by weakening of DE interaction, can decrease spin polarization of a manganite layer at the interface. Mitra *et al*. (2005) have demonstrated that stress-free LL LCMO/NGO films do not show nanoscale or mesoscopic PS; they possess rather homogeneous distribution of tunneling conductivity $\sigma = dI/dV_{0.1V} = 1.07–1.13\,\text{nA V}^{-1}$ over the measured area ($1 \times 1\,\mu\text{m}^2$) for $T < T_C$. The temperature dependence of tunneling conductivity shows a pronounced minimum by $T \sim T_C$, reflecting a bulk MI transition. No real insulating behavior with $\sigma = 0$ for $T > T_C$ was observed in agreement with results of Fäth *et al*. (1999). Very recently, Moshnyaga *et al*., (2006) have prepared LCMO/MgO films, showing unusual rhombohedral R-3c crystalline structure and unique ordering of A-site cations (La and Ca). Note that the relatively small ionic radius of Ca leads to the formation of orthorhombic P_{nma} structure (Radaelli *et al*., 1995, 1997) in LCMO manganites for the whole range of Ca doping ($0 < x < 1$). The A-site ordered film shows a unique superstructure with superlattice constant $a_s = 4a_{per} \approx 1.55$ nm due to ordered 3D arrangement of La and Ca cations. Such ordering suppresses (compensates) La/Ca size mismatch lattice stress within one supercell, resulting in a stress-free state of LCMO film. Remarkably, no PS on the scale down to 1 nm for $T < T_C$ was detected by STM/STS technique. In sharp contrast, an orthorhombic LCMO/MgO film does show PS for $T < T_C$, similar to the results of Fäth *et al*. (1999); Becker *et al*. (2002); Chen *et al*. (2003) with the size of insulating clusters 10–50 nm. No correlation with morphology (microstructure) was observed, indicating intrinsic nature of PS.

Thus, we believe that realization of tendencies to PS should be closely related to the crystallographic structure. As was shown in Section 1, the structure close to cubic ($t \sim 1$) favors DE interaction resulting in FMM behavior. Typical example is a canonic DE material LSMO, which being optimally doped shows high-$T_C{\sim}360$ K, accompanied by second-order phase transition; to the best of our knowledge no PS was observed in such LSMO up to now. By lowering the crystal symmetry down the orthorhombic, the competing EL interaction increases, leading to PS in the presence of cation disorder, imposed on the first-order phase transition (LCMO).

4.1.3 Percolative MI transition and CMR effect

The electronic inhomogeneity revealed by STM/STS technique in thin manganite films (Fäth *et al*., 1999; Becker *et al*., 2002; Chen *et al*., 2003; Moshnyaga *et al*., 2006) seems to be incompatible with polaronic scenario. This is because the

PS length scale, which varies in the range 10–100 nm, is much larger than the size of homogeneously distributed small polarons (Billinge *et al*., 1996; Kim *et al*., 1996; Jaime *et al*., 1997) and even larger than characteristic length of correlated polarons (Dai *et al*., 2000; Adams *et al*., 2000; Kiryukhin *et al*., 2003), which does not exceed 1–3 nm. The observed PS state rather assumes the existence of spatial fluctuations of stress and/or Coulomb potential due to quenched disorder (Moreo, Yunoki and Dagotto, 1999; Moreo *et al*., 2000; Dagotto, Hotta and Moreo, 2001; Burgy *et al*., 2001), discussed in Sections 2.3 and 2.4. Moreo *et al*. (2000) have obtained theoretically within one- and two-orbital models that the size of competing FM and AF clusters close to first-order phase transition in the presence of quenched disorder can be much larger than the lattice spacing. The cluster size varies in the range of few tens to few hundreds of lattice spacing; that is, within 10–400 nm. Moreover, the cluster size depends on the strength of disorder, σ^2, that is, the larger the disorder, the smaller the cluster size. The disorder-induced PS explains the observed inhomogeneities by STM/STS (Fäth *et al*., 1999; Becker *et al*., 2002; Chen *et al*., 2003; Moshnyaga *et al*., 2006) as well as those seen by TEM (Uehara, Mori, Chen and Cheong, 1999).

The important theoretical prediction was the *percolative* character of PS scenario as a function of magnetic field or temperature, intuitively concluded already in earlier experiments (Uehara, Mori, Chen and Cheong, 1999). Moreo *et al*. (2000) have shown that under applied magnetic field, the previously disconnected FM clusters grow in size and start to connect each other. Thus, a *percolation*, that is, formation of an infinite metallic cluster (Shklovsky and Efros, 1979), accompanied with formation of a current path emerges. The MI transition in the PS scenario occurs as a percolation transition within the two-phase model, simulated by the resistor network (Mayr *et al*., 2001). By decreasing temperature, starting from PM state, the concentration of metallic phase increases from zero up to a value called *percolation threshold*, p_0, which consists of 40 and 50% for 2D and 3D percolation models, respectively (Shklovsky and Efros, 1979). For $p > p_0$ a metallic filament builds up, forming the current path through the whole sample. Very large values of CMR $\sim 10^5\%$ (McCormack *et al*., 1994) can be quantitatively explained within the resistor network model, which shows that the resistance close to percolation threshold is very sensitive to small changes in concentration of metallic phase p, resulting in extreme large, up to several orders of magnitude, changes of the resistance (Mayr *et al*., 2001).

We proposed an approach (Moshnyaga *et al*., 2003; Lebedev *et al*., 2002) to create artificial phase-separated system, based on epitaxial nanocomposite manganite (LCMO) thin films, containing a second insulating phase (MgO), which chemically and crystallograhically fits the primary manganite phase. Such composites can be viewed also as an artificially created 'phase-separated' system, consisting of 3D manganite nanoclusters, imbedded in an appropriate insulating oxide matrix. Thus, chemical PS will lead to an artificial EPS of the MI type, parameters, and the scale of which can be controlled by processing conditions. Magnetotransport properties can then be compared with those recently observed in 'naturally existing' electronic phase-separated samples (Uehara, Mori, Chen and Cheong, 1999). The microstructure of $(LCMO)_{1-x}$:$(MgO)_x$ nanocomposite films grown on MgO substrate by MAD technique is shown in Figure 19. In the cross-sectional image (Figure 19a), one can see that both LCMO and MgO phases grow epitaxially on the MgO substrate. The mean diameter of the LCMO domains varies as $D = 40–50$ nm. Sharp interfaces are also seen in an HREM plane view image in Figure 19(b). Remarkably, we did not observe misfit dislocations at these LCMO/MgO interfaces similar to the case of individual LCMO films grown on

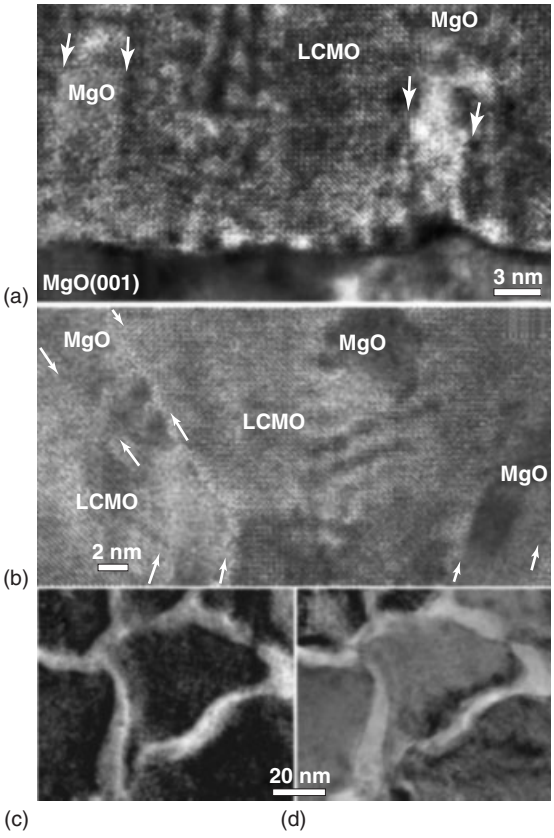

Figure 19. Cross section (a) and plane view (b) HREM images of epitaxial nanocomposite (LCMO):(MgO) films. Mg (bright) map obtained by EELS (c) and plane view TEM image (d) of the same region showing clear chemical phase separation between LCMO and MgO. (Reproduced from V. Moshnyaga *et al*., 2003, with permission from Nature Publishing Group. © 2003.)

MgO substrate by MAD technique (see Section 3.3). Energy filtered TEM in a plane view, shown in Figure 19(c), demonstrates no chemical intermixture between LCMO and Mg (bright regions), which is in good agreement with the sharp contrast between these phases in the HREM image (Figure 19d). Thus, we conclude that composite films contain chemically well-separated nanocrystalline LCMO and MgO domains, which are epitaxially oriented with respect to each other as well as to the substrate. By varying the concentration of MgO, x, one can control magnetotransport behavior as we as the structure of the LCMO phase. The percolation threshold in conductivity was found for $x_c = 0.33$. This means that for $x > x_c$ resistivity at room temperature drastically increases as shown in Figure 20 and no MI transition at zero (ambient) magnetic field was observed for temperatures down to 4.2 K. Remarkably, in such artificial PS system, the CMR effect is manifested as a field-induced MI transition (see Figure 20) and exactly at the percolation threshold CMR reaches very large values of more than $10^5\%$ for B = 5 T. This is in very good agreement with computational models (Mayr *et al*., 2001) and probably explains the nature of very large CMR in earlier experiments (McCormack *et al*., 1994) as really caused by the PS scenario. Another interesting result of this study (Moshnyaga *et al*., 2003) was the observation of strong elastic coupling between the LCMO and MgO nanophases. This coupling provides an additional opportunity to control the behavior of LCMO by means of volume tensile stress or 'negative' pressure, actuated by MgO second phase. As a result, the structure of LCMO changes from a usual orthorhombic (P_{nma}) to the rhombohedral (R-3c), which is shown on the phase diagram in Figure 20(b). The structural phase transition (see Figure 20b) occurs also at the percolation threshold, when an infinite MgO cluster emerges, connecting all LCMO domains and yielding homogeneous and very large volume stress. According to Lebedev *et al*. (2002), this structural phase transition to a more symmetric rhombohedral phase provides a stress accommodation mechanism, which is necessary to release very large bulk tensile stress induced by the MgO second phase.

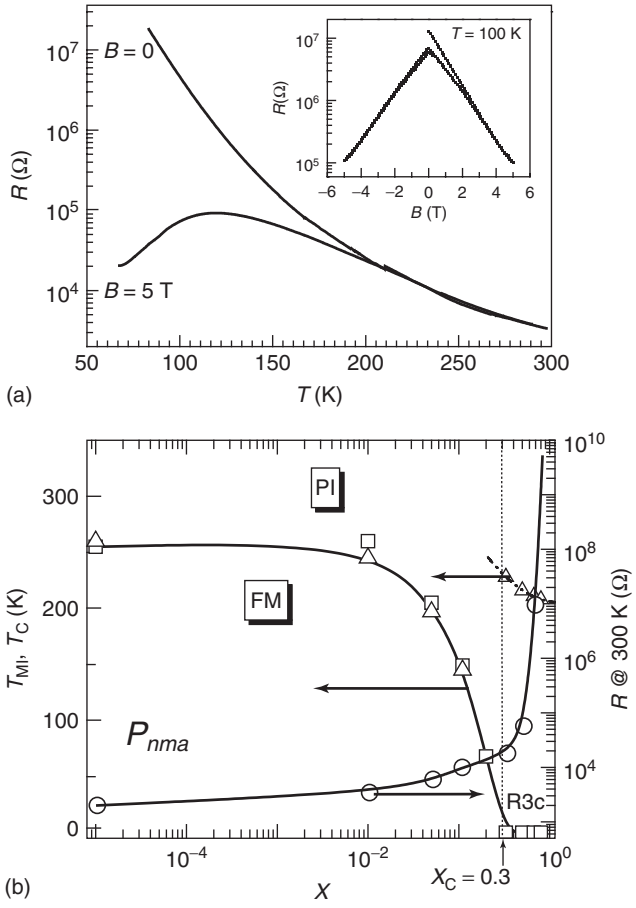

Figure 20. CMR effect as magnetic field-induced metal-insulator transition at the percolation threshold for $x = 0.33$ (a) and phase diagram of LCMO:MgO system (b), showing tight coupling between structural, magnetic, and electronic properties. 4.2 Low-field magnetoresistance

As is commonly believed, the CMR effect being limited within narrow temperature region close to T_C and strong magnetic fields of several Tesla has no potential for applications. The device applications like magnetic sensors or magnetic random access memory (MRAM) require both low-field sensitivity and broad operation temperature region. The low-field sensitivity is provided with the TMR effect on the interfaces between manganite and insulating phase (usually STO). The structure of such interfaces realized in planar geometry or as GB was discussed in Section 3.2. Another possibility for low-field MR provides intrinsic magnetic disorder, that is, magnetic domain structure naturally existing in a FM material. For low-field applications one can try to use the interaction between the transport current, $\vec{J}$, and fluctuations of magnetization vector $\overrightarrow{M}$ in a structurally homogeneous ferromagnet because of two different MR effects: (i) direct scattering of charge carriers on domain walls, called *domain-wall magnetoresistance* (*DWMR*) and (ii) spin-orbit interaction induced difference in scattering amplitude when the current flows parallel and perpendicular to the magnetization direction, called *anisotropic magnetoresistance* (*AMR*). In the following text we discuss these low-field MR effects with respect to manganite films, but concentrate first on the TMR effect.

4.2.1 Tunneling magnetoresistance (TMR)

The main idea of TMR is based on spin-dependent scattering of charge carriers (Moodera, Kinder, Wong and Meservey, 1995), which are assumed to be spin polarized, that is, the electrons possess a definite projection of spin, on the interfaces (see Figure 21). Because of broken translational symmetry of the manganite films on the interfaces, there are two magnetically decoupled manganite layers (electrodes), having in between an insulating tunneling transparent barrier layer with the thickness typically about 1–2 nm. When a dc bias is applied electrons can tunnel through the barrier. The resistance of such magnetic tunnel junction depends on the relative orientation of magnetization in FM electrodes for $T < T_C$, which can be controlled by applied magnetic field. The TMR ratio is

$$TMR = (R_{AP} - R_P)/R_{AP} \tag{7}$$

With R_{AP} and R_P are resistances of magnetic tunnel junction for antiparallel and parallel orientation of magnetization

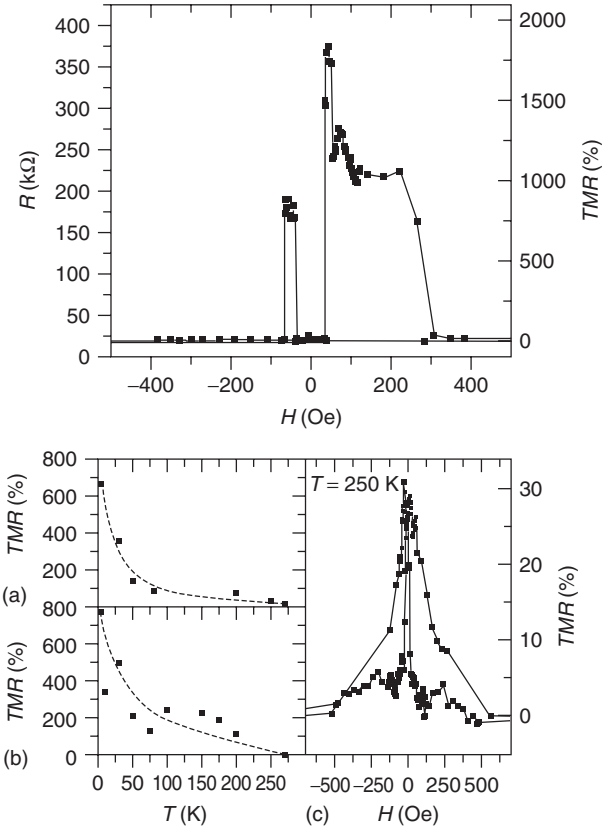

Figure 21. Field dependence of the resistance of a magnetic tunnel junction from (upper panel) and temperature dependences of the TMR effect (lower panel). (Reproduced from M. Bowen *et al.*, 2003, with permission from the American Institute of Physics. © 2003.)

of electrodes, respectively (Bowen *et al.*, 2003). $R_P < R_{AP}$ because, under assumption that spin of charge carrier does not changes by tunneling process, the parallel configuration account for minimum energy while to realize the antiparallel configuration an additional energy to reorient spin of an electron is required. Julliere (1975) has formulated that TMR ratio of a magnetic tunnel junction depends on the spin polarization of electrons on the Fermi level in both electrodes, P_1 and P_2, as the following:

$$TMR = 2P_1P_2/(P_1 - P_2) \tag{8}$$

The advantage of manganites for TMR is that the spin polarization, as measured by spin resolved photoemission spectroscopy, can be very high reaching almost 100% (Park *et al.*, 1998). One calls manganites *half-metallic* with practically fully spin polarized electrons on the Fermi level. In comparison, spin polarization of transition element FM metals like Fe, Ni, or Co does not exceed 50% (Monsma and Parkin, 2000), yielding usually maximum TMR $\sim$ 60%. According to Julliere's model, manganites should show very high TMR, which even can diverge when $P_1 = P_2 = 1$. On the other hand, by constructing a magnetic tunnel junction, one electrode of which has known P value, one can estimate the spin polarization for another electrode. Indeed, manganite base tunnel junctions (Bowen *et al.*, 2003), prepared as trilayer structure LSMO/STO/LSMO, reveal extremely high TMR = 1800% as shown in Figure 21. One can see that resistance change can exceed 1 order of magnitude for very low magnetic fields, comparable to coercive field $H_C \sim 100$ Oe. The estimated spin polarization degree in LSMO was 95% in good agreement with spectroscopy measurements (Park *et al.*, 1998). However, such high TMR value was observed only for low temperatures. In Figure 21(b) one can see that TMR decreases strongly with increasing temperature and even for $T \sim$250 K, that is, much lower than bulk $T_C = 360$ K for LSMO TMR vanishes. Similar temperature dependences were obtained on TMR structures prepared by different techniques with tunneling barriers grown between planar interfaces, vertical interfaces as well as a GB (Hwang, Cheong, Ong and Battlog, 1996; Steenbeck *et al.*, 1998; Gupta *et al.*, 1996; Phillip *et al.*, 2000; Lu *et al.*, 1996; Sun *et al.*, 1996; Pailloux *et al.*, 2002; Luo and Samwer, 2001; Köster *et al.*, 2002), thus indicating a common temperature behavior of TMR in manganite-based magnetic tunnel junctions. The degradation of T_C and, hence, of spin polarization in the manganite layer close to the interface caused, likely, by stress effect or interface doping was suggested. Commonly used barrier material, STO, with small lattice mismatch, $\varepsilon \approx 0.9\%$ indeed induces coherent strain in LSMO layer up to about 100 nm distance from the barrier, leading to decrease of T_C for LSMO from the bulk value 360 down

to 310 K in the strained film (Izumi *et al*., 1998). However, such reduction of T_C does not explain the suppression of TMR for temperatures much lower than room temperature. Moreover, the LCMO/NGO/LCMO tunnel junctions (Moon-Ho, Mathur, Evetts and Blamire, 2000) with perfectly matched NGO barrier also show drastic reduction of TMR for temperatures around 150–200 K, that is, far away from bulk T_C of LCMO as discussed in the following text.

An interesting way to increase the interface magnetization of LSMO and thus to increase spin polarization at room temperature was proposed by Yamada *et al*. (2004). They suggested that degradation of the interface magnetization occurs because of the doping effect, that is, of increased Sr concentration on the interface resulted from the SrO termination layer of $SrTiO_3$ barrier. By means of interface LL engineering, they introduced a two-unit-cell-thick LMO between the LSMO/STO interface. As a result, the interface magnetization, probed by second-harmonic-generation (SHG) technique, was significantly increased at room temperature. Without LMO layer no magnetic SHG was observed already for $T \sim 250$ K. Another source of interface degradation (Bibes *et al*., 2001), is related to a nanoscale PS on the LCMO/STO interfaces induced by coherent strain effect. As a result, the FM coupling within the metallic regions is depressed. This accounts for the reduction of the Curie temperature and conductivity in the manganite layer close to the interface. Although the precise cause for the reduction of interface magnetism (stress, disorder, doping, PS, etc.) is difficult to determine in any concrete case, from structural considerations it seems probably that the problem is closely related to the interface symmetry of d orbitals of Mn, resulting in the change of Mn–O bond length and/or O–Mn–O angle, which both are crucial for magnetism in manganites. In this sense very important becomes the problem of termination layer, that is, whether (La,Sr)O or MnO_2 layer terminates a manganite film at the interface. Pailloux *et al*. (2002) have shown that (La,Sr)O termination does not disturb average valence of Mn close to interface and allows one to keep TMR still measurable close to the bulk T_C in Co/STO/LSMO tunnel junctions. Interesting interface properties were shown by Giesen *et al*. (2004), who observed that all-manganite multilayers like $(LSMO/LCMO)_n$, prepared by PLD technique, do not show PS induced reduction of magnetic and electric properties of LCMO layer down to the thickness of 6 nm. This was interpreted within the preservation of Mn–O–Mn chains at the interfaces. In this context, an insulating manganite barrier layer for TMR structures looks very interesting (Kleine, Luo and Samwer, 2006). One can suppose that LMO with the same perovksite structure and practically the same lattice parameter as electrodes (LSMO) would not suppress interface magnetism in LSMO.

4.2.2 Domain-wall and anisotropic magnetoresistance (DWMR and AMR)

The information on the DWMR in manganite films (Mathur *et al*., 1999; Wolfman *et al*., 2001; Ziese, 2002) is limited and contradictory. This is caused by the fact that both DWMR and AMR effects lead to very small relative changes in the resistance, $\Delta R/R \leq 0.1$–1 %, which can be hardly separated between DWMR and AMR effect and/or can be even hindered by other extrinsic (TMR) or intrinsic (CMR) effects (Ziese, 2002). Moreover, the observation of DWMR requires a definite geometry of magnetic domain structure, which is usually achieved by the preparation of nanocontacts and nanoconstrictions. Micromagnetic simulations of the domain structure accounting additionally for stress-induced changes in magnetic anisotropy in thin manganite films (O'Donnell, Rzchowski, Eckstein and Bozovic, 1998) are also extremely important. To obtain reliable experimental data, well-defined samples made from epitaxial thin films of high crystalline quality, usually grown by LL mode, are required. Mathur *et al*. (1999) have seen a step like of about 1% jumps in the resistance at T = 77 K of a LCMO thin-film array, containing constricted areas of micrometer size, which were assumed to pin the domain walls close to constrictions. The estimated value of domain wall × area resistance, DWRA = $8 \times 10^{-14} \Omega m^2$, was about 4 orders of magnitude smaller than that for a grain boundary, but much larger than DWRA in FM cobalt. The DWMR = 16% at room temperature was obtained for a LSMO film with a nanoconstricted area, produced by electron beam lithography (Wolfman *et al*., 2001). In Figure 22, the vertical nanoconstriction geometry with $h = 90$ nm-wide gaps lying in the film plane is shown. The resistance of a such nanobridge as a function of magnetic field shows very sharp 1.8 kΩ large jumps for $H \sim 0.75$–1.5 kOe with a hysteresis in switching, thus evidencing magnetic origin of the resistance change. The very large resistance × area product DWRA = $10^{-11} \Omega m^2$ implies that the width of domain wall is strongly reduced due to nanoconstriction.

The AMR effect, which is governed by the magnetization state of a structurally homogeneous FM material, seems to be more appropriate for low-field applications (Ciureanu and Middelhoek, 1992) – at least no special geometric limitations like nanoconstrictions are required. Spontaneous AMR, originating from spin-orbit interaction (Smit, 1951; McGuire and Potter, 1975; Malozemoff, 1985), results in the anisotropy of the resistivity, $\Delta\rho = \rho_{||} - \rho_{\perp}$, with respect to the magnetization direction. Here $\rho_{||}$ and $\rho_{\perp}$ is the resistivity parallel and perpendicular to the magnetization direction, respectively, of a single-domain ferromagnet. Depending on whether the voltage is probed parallel (V_X) or perpendicular (V_Y) to the current density, the electric field related to the AMR is given

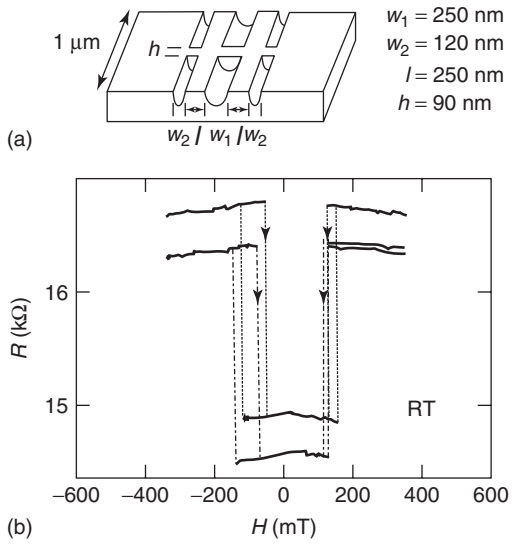

Figure 22. (a) Scheme of a nanoconstriction device and (b) field dependence of the resistance at room temperature. (Reproduced from J. Wolfman *et al*., 2001, with permission from the American Institute of Physics. © 2001.)

by Li *et al*. (1999):

$$E_x = j\rho_\perp + j(\Delta\rho)\cos^2\alpha \quad \text{(Longitudinal geometry)} \quad (9)$$

$$E_y = (j/2)(\Delta\rho)\sin(2\alpha) \quad \text{(Transverse geometry)} \quad (10)$$

Here, j is the transport current density in x direction, and α is the angle between current and the magnetization. AMR is quantified by a ratio $\gamma = \Delta\rho/\rho_0$ (ρ_0 is bulk resistively of the material at zero filed), which is only about 1% for most FM materials as well as for magnates (Mathur *et al*., 1999; Malozemoff, 1985; Li *et al*., 1999). Therefore, AMR, usually hardly seen in longitudinal geometry ($\Delta\rho \ll \rho_\perp\rho_0$), can be detected in the transverse geometry (equation (10) using a properly microstructured epitaxial films.

We have studied in detail the AMR effect in transverse geometry (also known as *planar Hall effect*) for epitaxial $La_{0.7}(Ca_{0.5}Sr_{0.5})MnO_3$ (LSCMO, $T_C = 310–320$ K) thin films grown by MAD technique (Moshnyaga, Damaschke, Tidecks and Samwer, 2003) and built a prototype low-field manganite sensor operating at room temperature. The film was patterned photo-lithographically as shown in Figure 23. The length of the current line was $L = 6$ mm and the width $W = 0.3$ mm. The transverse voltage was detected with the V_Y contacts placed in the perpendicular direction. The magnetic field was aligned parallel to the film surface. The angle dependence of the transverse voltage, $V_Y(\alpha)$, measured at room temperature and magnetic field $H = 0.5$ kOe (see Figure 23) obeys equation (9) for the AMR effect, corrected

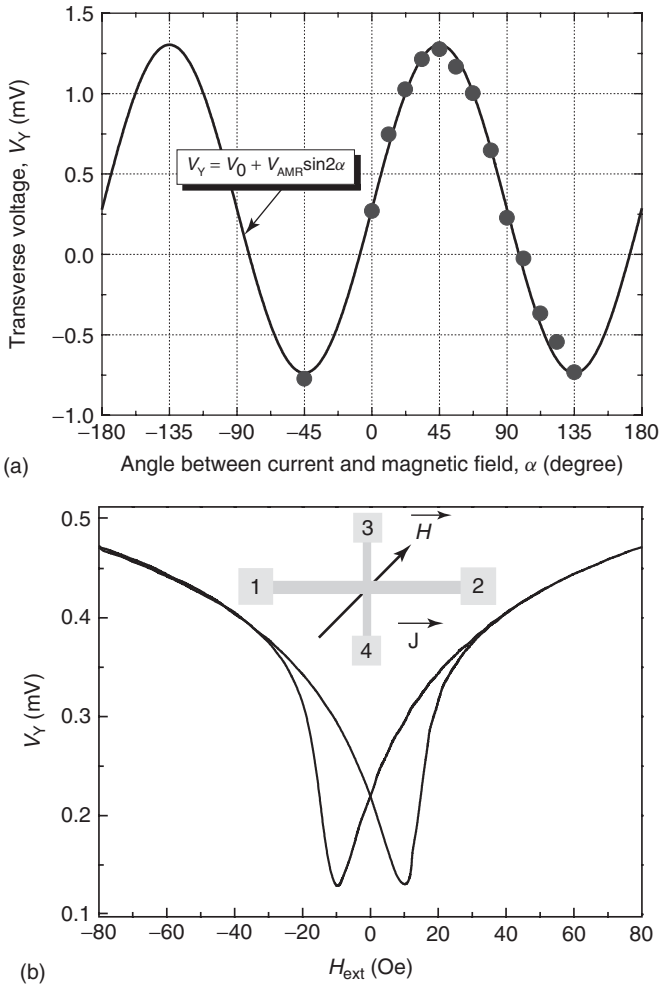

Figure 23. Angle (a) and magnetic field (b) dependences of transverse voltage of a $La_{0.7}(Ca, Sr)_{0.3}MnO_3$ thin film. The sample geometry is shown in the inset of (b): the current flows between contacts (1,2) and the voltage, V_Y, is measured between the opposite contacts (3,4). Magnetic field is aligned parallel to the film plane at angle α to the current line. (Reproduced from V. Moshnyaga *et al*., 2003a, with permission from the American Institute of Physics. © 2003.)

by small isotropic offset voltage, V_0, due to longitudinal misfit of the transverse contacts:

$$V_Y(\alpha, H) = V_0(H) + V_{AMR}(H) \times \sin(2\alpha) \quad (11)$$

here: $V_0 = 0.27$ mV and $V_{AMR} = 1$ mV for $H = 0.5$ kOe. As one can see in Figure 23(b) the magnetic field dependence of the AMR voltage in the LSCMO films is extremely sharp for very low fields $H = 0–20$ Oe, yielding a maximum room-temperature field sensitivity of $S \approx 20\%$/Oe. Another important quantity is the magnetovoltage ratio, $MV = 100\%[V_{AMR}(H)/V_0]$, which describes the relative change of the transverse voltage in an applied magnetic field.

For $\alpha = 45^\circ$ and $H = 500\,\text{Oe}$ with $V_{\text{AMR}} = 1\,\text{mV}$ and $V_0 = 0.25\,\text{mV}$ (see Figure 18) we get MV = 400%. Even for very low fields, $H < 40\,\text{Oe}$, it is $MV\,(40\,\text{Oe}) = 220\%$. The mentioned parameters for manganite films considerably exceed $S = 6\%/\text{Oe}$ and $MV = 130\ \%$ at $H = 35\,\text{Oe}$, observed for the transverse AMR structures based on Co/Ni multilayers at room temperature (Prados *et al*., 1995). Very recently, by improving the measurement conditions of LSCMO-based prototype thin-film sensor, we obtained the output sensitivity as large as $S = 400\,\mu\text{V}\,\text{Oe}^{-1}$ for very low-field $H \sim 1\,\text{Oe}$. With the actual noise level, $V_{\text{N}} \sim 0.1\,\mu\text{V}$, the dc magnetic field sensitivity was $H_{\text{N}} = V_{\text{N}}/S \approx 2 \times 10^{-4}$ Oe at room temperature. All this makes manganite-based MR sensors very attractive for a low-field sensing, which was already demonstrated by us at the International Hannover fair, 1–24 April 2004.

5 SUMMARY AND OUTLOOK

We hope that in spite of limited space, the main features of the physics of manganite thin films were discussed. The most important and most intriguing aspect of the manganites is definitely their *complexity*, related to a rich variety of experimentally observed physical effects like MI transition, CMR, charge, and OO. These phenomena, mediated by different electronic and structural phase transitions, can be strongly influenced by external stimuli (field, temperature, pressure, electromagnetic radiation), resulting in potentially useful effects.

Furthermore, the complexity of manganite also includes the coexistence of different electronic and structural phases (*PS*) as well as the interaction between them. The nature of phase competition or in other words the mechanisms of interaction between different phases within PS scenario seems to be most difficult and thus unexplored problem both for experimental and theoretical physics. Taking into account the major role of lattice strain and disorder effects on the structure and electronic properties of manganites, discussed in Section 1, one can suppose that the phases, FMM and AFI, counteracting in the PS scenario, may be *coupled elastically*. From earlier fundamental studies it is known these phases differ by their crystalline structure (AFI phase is orthorhombic and FMM phase is cubic or rhombohedral) and thus by degree of lattice strain. This point seems to be in good agreement with local STM/STS. Moreover, the observed nonmonotonous magnetic field dependence of the local tunneling conductivity map as well as the irreversibility and 'magnetic history' effects in the PS in thin films of LCMO strongly support the coupling between phases. Note that the irreversibility close to the orthorhombic-rhombohedral structural phase transition in bulk $La_{1-x}SrMnO_3$ (x = 0.17) was clearly seen not only by changing temperature but also as a function of magnetic field, known as *structural phase transition induced by magnetic field* (Asamitsu *et al*., 1995). More generally temperature and magnetic field behavior of the PS in thin films as well as its characteristic scale (10–100 nm) agrees well with the disorder (stress)-induced PS scenario close to the first-order phase transition. Very important becomes the issue of controlling cation disorder, which will allow one to study CMR and electronic manifestations of small and correlated polarons on a very fine scale (1–3 nm) in a so-called *clean limit*. We believe the first step along this line is done by means of preparation of A-site ordered LCMO films.

Along the fundamental importance, the controlling of stress and disorder on the nanoscale seems to be interesting also for future applications. We would like to draw the attention of the reader to the following, may be unexpected, aspect of the PS model: the interaction between metallic and insulating phases occurs at the *interfaces and by means of changing of the interface properties*. This implies also that PS dynamic as a function of field or temperature should be strongly dependent on the interface quality. One can find a very clear analogy with the magnetic tunnel junctions, the performance (spin polarization) of which as we have seen in Section 2.2 depends crucially on the interface quality. Thus, to control PS with a possibility to make a step in nanoscale physics and technology down to at least 10 nm as well as to control the TMR device performance means to be able to control the interfaces. The term *interface engineering* is already known. With respect to the PS problem such interface nanoengineering can be done by creating 'static' interfaces in the preliminary homogeneous electronic template chemically by doping during self-assembled growth of nanophases, like in LCMO:MgO nanocomposites. In this sense, the search of new phase counterparts and further technological development are necessary. Even more interesting seems to be 'dynamic' interfaces created by electromagnetic radiation. It is known that electromagnetic radiation (X ray or visible light) can significantly change the ground state of a manganite resulting even in insulator–metal transition (see for example, Kiryukhin *et al*., 1997; Mishina *et al*., 2004); this topic is out of the frame of this review). However, locally the effect of electromagnetic radiation on the PS was not studied to the best of our knowledge.

Recently, *multiferroic behavior* has become a very hot topic. Such materials combining FM and FE properties are extremely interesting both for fundamental and applied science (Spaldin and Fiebig, 2005). Such materials would, in principle, allow one to get new functions due to magneto-electric effect, that is, magnetization can be controlled by electric field and, vice versa, electrical polarization can be changed by magnetic field. Because of a limited amount of

intrinsic multiferroic materials (note that FM-FE coexistence in the same chemically homogeneous material seems to be mutually exclusive – FE needs empty but FM requires partially filled transition-metal orbitals (for details see Spaldin and Fiebig, 2005)), there is a great demand of composite multiferroic materials, among which thin-film composite will play a major role owing to the possibility of obtaining very large interface area and thus of optimizing elastic coupling between FM and FE constituents with corresponding optimization of magnetoelectric effect. In this case, the problem of controlling thin-film interfaces becomes extremely important. Recently, Zheng *et al*. (2004) have prepared multiferroic $BaTiO_3$–$CoFe_2O_4$ film nanostructures, in which elastically coupled nanocolumnar phases are also coupled magnetoelectrically, that is, magnetization of $CoFe_2O_4$ changes at the FE Curie temperature. It seems reasonable to substitute $CoFe_2O_4$ in such a composite with a manganite (LCMO) phase; the latter should be much more sensitive to mechanic deformation actuated anyway by the FE $BaTiO_3$ component. However, to realize chemical PS (not multilayer geometry) between two phases (LCMO and $BaTiO_3$) having the same perovskite structure looks quite a challenging task for thin-film technology.

1 INTRODUCTION

Ferromagnetic semiconductors are semiconductors that exhibit ferromagnetism. Owing to spontaneous spin splittings in the band structure caused by exchange interaction, they exhibit a variety of spin-dependent optical and transport properties that are not readily available in other materials. Owing to this additional spin degree of freedom, ferromagnetic semiconductors can combine semiconductor heterostructure physics and ferromagnetism, which may lead us to new usage of semiconductor properties and ferromagnetism that was not realized by other systems (Awschalom, Loss and Samarth, 2002; Žutić, Fabian and Das Sarma, 2004). The study of ferromagnetic semiconductors was initiated by extensive theoretical and experimental studies on rare-earth chalcogenides and chromite spinels since the 1960s (Methfessel and Mattis, 1968; Holtberg *et al*., 1980; Mauger and Godart, 1986). However, difficulties in preparation of materials and their heterostructures made these materials less attractive. Recent progress in ferromagnetic semiconductors was made in a class of semiconductors called *diluted magnetic semiconductors* (DMSs), where a part of host atoms is replaced by magnetic elements. In the early stage of the DMS research, studies were done on paramagnetic II–VI compound semiconductor-based DMSs (Furdyna and Kossut, 1988; Kossut and Dobrowolski, 1993; Dietl, 1994). These paramagnetic II–VI DMSs showed antiferromagnetic superexchange interaction among magnetic ions and exhibited a number of new spin-dependent phenomena including giant Zeeman splitting of band states induced by an external magnetic field H. Giant Zeeman splitting is caused by the exchange interaction among band carriers (sp states) and magnetic spins (d states), which is often called the *sp–d exchange interaction*. This interaction is the source of most of the unique properties of II–VI DMSs and determines properties such as the magnitude of the Faraday effect and allows one to realize a new class of low-dimensional structures, such as spin superlattice (Kossut, 2001; Dobrowolski, Kossut and Story, 2003).

Synthesis (Munekata *et al*., 1989) and subsequent discovery of ferromagnetism in III–V-based DMSs, (In,Mn)As and (Ga,Mn)As, in the 1990s (Ohno *et al*., 1992, 1996) added a new dimension to the magnetic semiconductor research because of possible seamless integration of ferromagnetism with well-established III–V heterostructures and devices. (Ga,Mn)As and (In,Mn)As are now most well-investigated and well-understood ferromagnetic semiconductors and the material and their heterostructures provide an ideal test

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

bench for demonstrating new concepts in physics and device operation (Ohno, 1999; Matsukura, Ohno and Dietl, 2002; Jungwirth *et al*., 2006). It has been established that the existence of holes brings about the ferromagnetic interaction among Mn spins in (Ga,Mn)As and (In,Mn)As. The p–d Zener model has been shown to describe qualitatively and, in many cases, even quantitatively a number of experimental results on these materials (Dietl, Ohno and Matsukura, 2001; Dietl *et al*., 2000). In this review, we intend to summarize the present state of the experimental results on ferromagnetic semiconductors focusing mainly on the prototypal (Ga,Mn)As and (In,Mn)As and their device structures.

2 PREPARATION AND BASIC CHARACTERIZATION

A number of methods have been employed for the synthesis of DMSs. These include Bridgman and Czochralski methods for bulk materials, and molecular-beam epitaxy (MBE), diffusion, ion implantation, and pulsed-laser deposition methods for thin films. The Bridgman method was adopted to obtain single-crystal bulk II–VI DMSs, in which the solubility of transition metals can be high due to the isoelectronic nature of magnetic ions; for example, highest Mn composition $x \sim 0.8$ for representative II–VI DMS, $Cd_{1-x}Mn_xTe$ (Furdyna and Kossut, 1988). MBE growth has been adopted for nearly all heterostructures and low-dimensional structures based on II–VI materials. It has also been used to prepare (In,Mn)As with $x < 0.18$ (Munekata *et al*., 1989), overcoming the solubility limit of transition metals in III–V, which is of the order of 10^{18}–$10^{19}\,cm^{-3}$, together with the surface segregation and phase separation (DeSimone, Wood and Evans, 1982; Kordoš, Janšák and Benč, 1975). The growth of single-crystal (In,Mn)As was achieved by employing low-temperature molecular-beam epitaxy (LT-MBE), performing epitaxial growth at low growth temperature T_S below 300 °C compared to typical $T_S \sim 500\,^{\circ}C$ for InAs, where, importantly, T_S was still high enough to provide metastable single crystal and low enough to suppress the formation of thermodynamically stable second phases such as MnAs. This initial success of (In,Mn)As was followed by the growth of (Ga,Mn)As (Ohno *et al*., 1996). Most of Mn in III–V DMSs substitute the third-group cation site and provide both localized spins and holes due to their acceptor nature.

2.1 Molecular-beam epitaxy of (Ga,Mn)As

Typical MBE of (Ga,Mn)As is carried out in an ultrahigh vacuum MBE chamber with elemental sources, Ga, Mn, and As, on GaAs(001) substrates with surfaces under As-stabilized conditions. After the removal of surface oxide and the growth of buffer layer for the preparation of a flat starting surface, the growth of (Ga,Mn)As is initiated by simply commencing the Mn flux during the LT-GaAs growth while keeping T_S constant at ∼250 °C. The reflection high-energy electron diffraction (RHEED) pattern is used as a common tool to monitor the growth front. The RHEED pattern for (Ga,Mn)As shows a streaky (1 × 2) pattern, confirming the growth of (Ga,Mn)As with a zinc-blende structure. Maximum x reported so far is 0.15 (Chiba, Takamura, Matsukura and Ohno, 2003). When T_S and/or Mn flux is too high, one can recognize the segregation of the hexagonal MnAs phase from a spotty RHEED pattern (Shen *et al*., 1997a). Further decreasing T_S or employing the migration-enhanced epitaxy (MEE) method, where Ga + Mn and As fluxes are supplied alternately, have been reported to help increase maximum x, but not dramatically (Takamura, Matsukura, Ohno and Ohno, 2001; Sadowski *et al*., 2001). If the growth condition is appropriate, a clear RHEED intensity oscillation is observed at the initial stage of growth (Shen *et al*., 1997a), where the surfactant effect of Mn and excess As may be responsible for the two-dimensional growth at low T_S (Shen, Horikoshi, Ohno and Guo, 1997b; Yasuda and Ohno, 1999; Guo *et al*., 2000). Magnetic and electrical properties of (Ga,Mn)As are strongly affected by the growth condition, such as V/III beam-flux ratio and T_S as well as x (Matsukura *et al*., 1999; Shimizu, Hayashi, Nishinaga and Tanaka, 1999; Ohno, 1998; Myers *et al*., 2006), which is related to the degree of compensation due to the existence of As antisites and Mn interstitials, both known as donors in GaAs.

2.2 Determination of Mn composition and lattice constants

Mn composition in the epitaxial film can be calculated from the beam-equivalent pressure (BEP) measured by an ion gauge inserted in the path of the beam flux and later calibrated to relate BEP to the beam flux and/or from the periods of the RHEED intensity oscillation observed at the initial stage of growth (Ohno *et al*., 1996; Sadowski *et al*., 2000). Other conventional analyses are also applicable, such as Auger microprobe measurement, electron probe-microanalysis (EPMA), and secondary ion mass spectroscopy (SIMS) (Ohno *et al*., 1996; Sadowski *et al*., 2001). Of all others, the most widely used method is the use of lattice constant a determined by X-ray diffraction (XRD) as the measure of x due to its experimental simplicity.

(Ga,Mn)As on a GaAs buffer layer has compressive lattice strain, and the free-standing lattice constant a is calculated with assumptions that the (Ga,Mn)As layer is fully strained, that is, the lateral lattice constant of the epitaxial layer is equal to the GaAs one, and that (Ga,Mn)As has the same elastic constant as GaAs (Ohno *et al*., 1996). The pseudomorphic growth without the indication of strain relaxation has been confirmed by asymmetric XRD at least up to a thickness of 2 µm with $x = 0.057$ (Shen *et al*., 1999). For (Ga,Mn)As, a is known to follow the Vegard's law, $a = a_{\text{LT-GaAs}}(1-x) + a_{\text{ZB-MnAs}}x$, where $a_{\text{LT-GaAs}}$ and $a_{\text{ZB-MnAs}}$ are the lattice constants of low-temperature-grown GaAs (LT-GaAs) ∼0.566 nm and hypothetical zinc-blende MnAs ∼0.598 nm respectively (Ohno *et al*., 1996). However, this way of determining a is known to suffer from uncertainties due to the degree of incorporation of defects like As antisites and Mn interstitials (Shimizu, Hayashi, Nishinaga and Tanaka, 1999; Hayashi, Hashimoto, Katsumoto and Iye, 2001; Schott, Faschinger and Molenkamp, 2001; Schott *et al*., 2003; Sadowski and Domagala, 2004).

Most of Mn in (Ga,Mn)As substitutes Ga; that is why we write this alloy as (Ga,Mn)As. For Mn-doped GaAs,

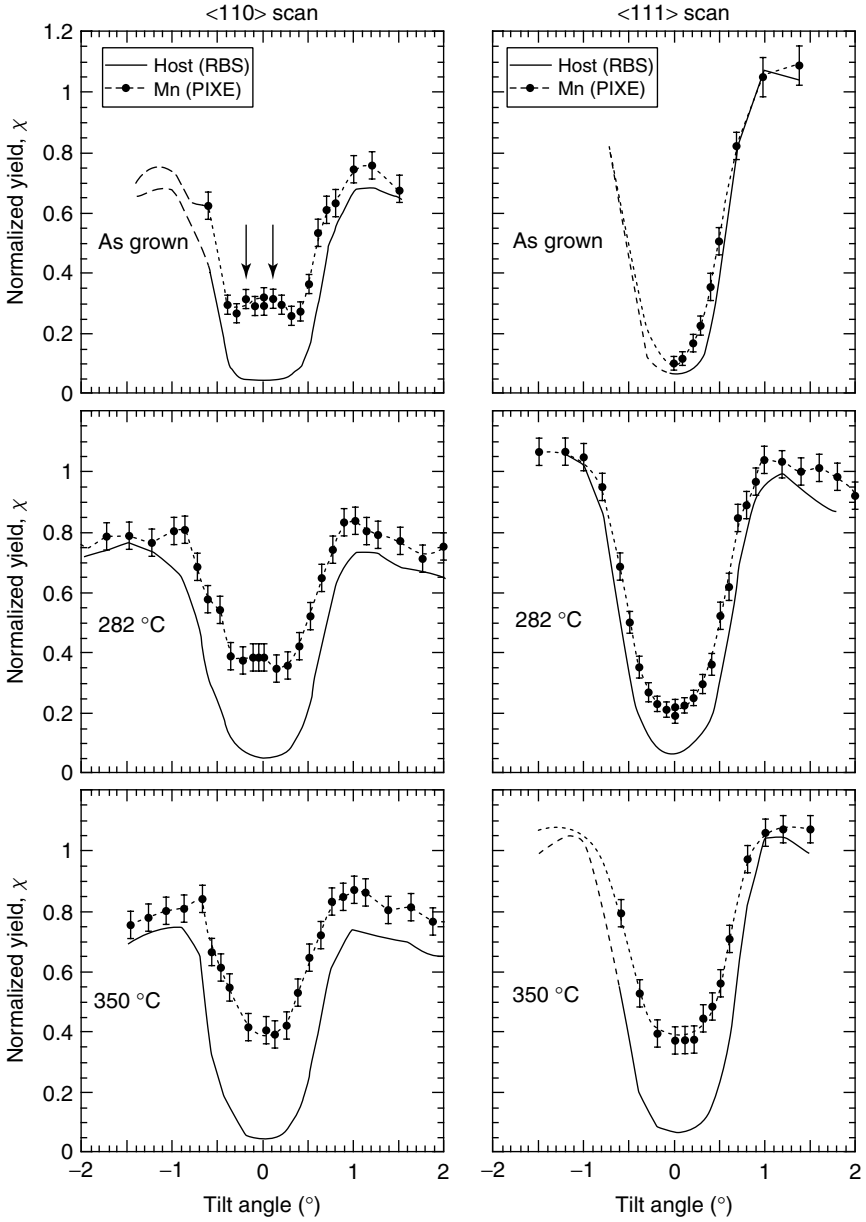

Figure 1. Angular scans of RBS and PIXE about ⟨110⟩ along {110} planar channel and ⟨111⟩ axes for three (Ga,Mn)As samples with $x \sim 0.08$ before and after LT annealing. (Reproduced from Yu *et al*., 2002, with permission from the American Physical Society. © 2002.)

with the doping level less than $10^{19}\,\mathrm{cm}^{-3}$, substitutional Mn was confirmed by an electron paramagnetic resonance (EPR) and cross-sectional scanning tunneling microscopy (XSTM) (Ilegrams, Dingle and Rupp, 1975; Schneider *et al*., 1987; Tsuruoka *et al*., 2002). For (Ga,Mn)As, the extended X-ray absorption fine structure (EXAFS) study showed that most of Mn are in the substitutional position, that is, on the Ga sublattice of the zinc-blende lattice (Shioda, Ando, Hayashi and Tanaka, 1998). The ion-channeling measurements (Rutherford backscattering (RBS) and particle-induced X-ray emission (PIXE)) shown in Figure 1 later revealed that those Mn atoms (∼17% of the introduced Mn atoms in the case of Figure 1) that were not incorporated in the substitional site reside in the interstitial sites (Yu *et al*., 2002a). Post-growth low-temperature annealing (LT annealing) at or below the growth temperature (Hayashi, Hashimoto, Katsumoto and Iye, 2001) was found to decrease the number of Mn interstitials, $\mathrm{Mn_I}$, and simultaneously increases hole concentration p (Potashnik *et al*., 2001; Edmonds *et al*., 2002a,b), indicating that the $\mathrm{Mn_I}$ is unstable and mobile donor. The double-donor nature of $\mathrm{Mn_I}$ is also shown from the *ab initio* calculation (Máca and Mašek, 2003). Further annealing at 350 °C results in MnAs precipitates having NiAs structure, which has T_C of ∼310 K. Theoretical study shows that double-donor $\mathrm{Mn_I}$ does not participate in ferromagnetic order and may form pairs with substitutional Mn, $\mathrm{Mn_{Ga}}$. This results in antiferromagnetic coupling by superexchange interaction and reduces net Mn moment (Blinowski and Kacman, 2003).

2.3 Determination of carrier concentration of (Ga,Mn)As

Since the presence of holes stabilizes ferromagnetism in (Ga,Mn)As, it is important to determine the hole concentration p. In conventional semiconductors, p can readily be determined by magnetotransport measurements, using the Hall effect. For ferromagnetic semiconductors, however, it is not straightforward due to the presence of the anomalous Hall effect, which can play a role even at room temperature, and of the negative magnetoresistance (MR) at low temperatures. Hall resistance R_{Hall} in ferromagnetic semiconductors is expressed as the sum of the ordinary Hall resistance and anomalous Hall resistance,

$$R_{\mathrm{Hall}} = \frac{R_0}{d}\mu_0 H + \frac{R_S}{d}M \qquad (1)$$

where R_0 and R_S are the ordinary and anomalous Hall coefficients respectively, d is the thickness of the ferromagnetic layers, M is the component of the magnetization perpendicular to the sample surface. R_S is usually proportional to $R_{\mathrm{sheet}}^{\gamma}$ (R_{sheet}: sheet resistance) with γ = 1 or 2, depending on the origin of the scattering (Chien and Westgate, 1980) or $\gamma = 2$ due to a scattering-independent topological contribution (Jungwirth, Qian and MacDonald, 2002). The dominance of the anomalous Hall term hinders the straightforward determination of the carrier type and concentration from the ordinary Hall term; the carrier concentration is given as $1/(eR_0)$ (e: elementary charge) and its positive (negative) sign corresponds to p-type (n-type) conduction. Only at low temperatures and under very high H, the anomalous Hall term almost saturates, so that R_0 can be determined from the remaining linear change of R_{Hall} in the H dependence, as shown in Figure 2 (Omiya *et al*., 2000; see also Sadowski *et al*., 2002; Edmonds *et al*., 2002a). Note that, although M saturates at relatively low H, negative MR persists to high H, and generates the H dependence of the anomalous Hall effect through the change in the anomalous Hall coefficient. Thus, this method is applicable only for (Ga,Mn)As with metallic conductivity because of the very large MR and resistance for insulating (Ga,Mn)As.

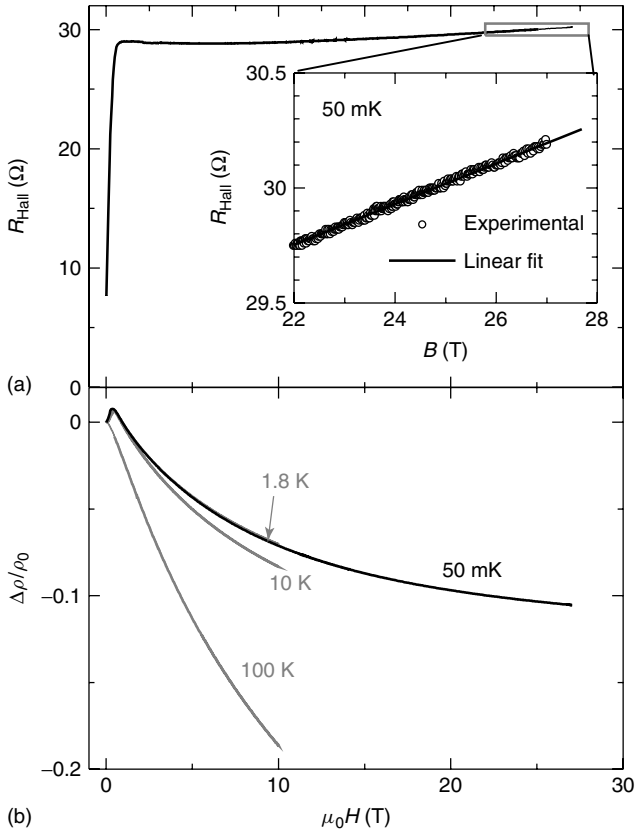

Figure 2. (a) R_{Hall} and (b) R_{sheet} measured at low temperatures. The inset shows that R_{Hall} is the linear function of H in the high-field region. (Reproduced from T. Omiya *et al*., 2000, with permission from Elsevier. © 2000.)

Another powerful method for determining p is the electrochemical capacitance–voltage (ECV) profiling. The reliability of this method was confirmed by comparison of p obtained from ECV and Hall measurements for Be-doped LT-GaAs (Yu *et al*., 2002b; see also Koeder *et al*., 2003; Moriya and Munekata, 2003). The determination of p by other methods, such as thermoelectric power measurements (Osinny *et al*., 2001) and the Raman scattering analysis of the coupled plasmon-LO-phonon modes, is also possible (Limmer *et al*., 2002; Seong *et al*., 2002).

These measurements revealed that p is often less than $10^{21}\,\mathrm{cm}^{-3}$ (smaller than nominal x) for as-grown samples, and increases significantly to $p = x$, consistent with the acceptor nature of Mn, after appropriate annealing as long as x is below 0.07 and the film is thin enough (Wang *et al*., 2004).

3 PROPERTIES OF (Ga,Mn)As

3.1 Magnetic properties

Magnetization M of (Ga,Mn)As is usually measured using a superconducting quantum interference device (SQUID) magnetometer. The diamagnetic response of thick GaAs substrate determined by a separate measurement must be subtracted from the measured magnetization curve in order to obtain the response from the thin epitaxial layer. When H is applied in the direction of magnetic easy axis of (Ga,Mn)As, M shows a sharp and clear hysteresis in its H dependence at low temperatures, which is one of the evidences of the presence of extended ferromagnetic order in the film. T_C can be determined by measuring the temperature dependence of the remanent magnetization, from the Arrott plots, and/or from the Curie–Weiss plot. The value of T_C has a strong correlation with the electrical conductivity, that is, for a given x, the T_C is higher for more metallic samples. The highest T_C reported so far is 173 K for (Ga,Mn)As with $x = 0.09$ after annealing (Wang *et al*., 2005a; Jungwirth *et al*., 2005). The p–d Zener model with mean-filed approximation is capable of explaining the observed magnetic properties, including the magnitude of T_C (Dietl *et al*., 2000; Dietl, Ohno and Matsukura, 2001).

The magnetic domain structure, which is another evidence of the presence of the extended ferromagnetic phase, has been observed in (Ga,Mn)As samples by a scanning Hall microscope and magneto-optical microscopes (Shono *et al*., 2000; Welp *et al*., 2003; Thevenard *et al*., 2006). The computed value of the domain width in (Ga,Mn)As by the p–d Zener model combined with micromagnetic theory (Dietl, König and MacDonald, 2001) is in reasonable agreement with the experimental ones.

3.2 Electrical properties

The spin–orbit interaction and the p–d exchange interaction manifest themselves in sizable magnetotransport phenomena, including the anomalous Hall effect, anisotropic magnetoresistance (AMR), and the planar Hall effect, which provide valuable information on the magnetism of (Ga,Mn)As. Because of the high sensitivity, the determination of magnetization behavior from transport is an important technique for thin films of diluted magnets, where the total of the magnetic moments is small. In addition, the sensitivity of transport measurements does not depend on the lateral size of the device with the fixed lateral aspect ratio.

The temperature and magnetic field dependence of R_{Hall} reflects the temperature and field dependence of magnetization because R_{Hall} is dominated by the anomalous Hall effect term of equation (1) (Matsukura, Ohno, Shen and Sugawara, 1998; Matsukura *et al*., 2004). From the same procedure as that for magnetization measurements, T_C can be determined by the Arrott plots and the Curie–Weiss plot, as shown in Figure 3 (Ohno and Matsukura, 2001). Since the (Ga,Mn)As layers grown directly on GaAs usually have in-plane magnetic easy axis, R_{Hall} measured in perpendicular H probes the magnetization process along the hard axis for the magnetization.

In contrast with R_{Hall} measured in perpendicular H, the planar Hall resistance is the transverse resistance measured by the same probes as R_{Hall} in an in-plane H (Jan, 1957). For (Ga,Mn)As, the signal of the planar Hall resistance is large and can be used to detect the in-plane M reversal (Tang, Kawakami, Awschalom and Roukes, 2003).

It has been found that MR of (Ga,Mn)As depends on the relative orientation of the current direction, the magnetic field direction, and their direction with respect to crystal axes (Hayashi *et al*., 2000). For metallic (Ga,Mn)As, the lowest resistance is observed when H is parallel to the current, as shown in Figure 4 (Baxter *et al*., 2002; Matsukura *et al*., 2004). The direction of H for the highest resistance, however, was predicted theoretically to be different for compressive and lattice strain (Jungwirth *et al*., 2002). This is corroborated by experiments; for the sample with compressive strain, the highest resistance is measured when H is perpendicular to the surface, and for the sample with a tensile strain it is observed when H is in-plane perpendicular to the current (Matsukura *et al*., 2004).

Resistance maximum observed around T_C and the negative MR associated with it are attributed to the critical scattering. The resistance maximum can be interpreted in terms of a spin-dependent scattering by packets of ferromagnetically coupled spins, whose correlation length is comparable to the wavelength of the carriers at the Fermi level. The

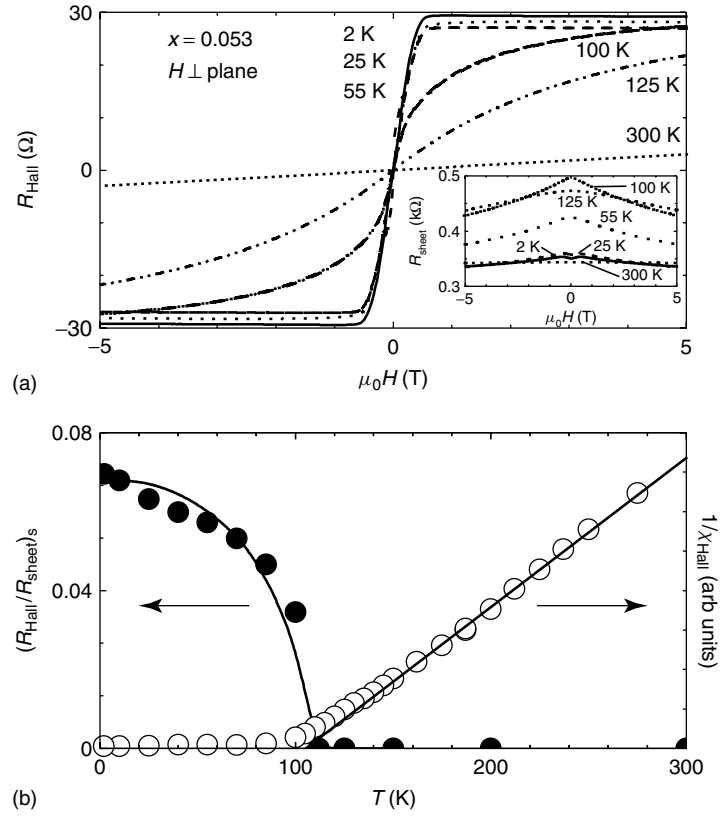

Figure 3. (a) Temperature dependence of R_{Hall} and MR (inset). (b) The temperature dependence of spontaneous magnetization, $(R_{\mathrm{Hall}}/R_{\mathrm{sheet}})_{\mathrm{S}}$ obtained from Arrott plots and the Curie–Weiss plot. (Reproduced from H. Ohno *et al*., 2001, with permission from Elsevier. © 2001.)

negative MR occurs because the H-induced spin alignment reduces the spin-disorder scattering (Matsukura, Ohno, Shen and Sugawara, 1998). From the numerical fitting to the data of the temperature dependence and H dependence of the resistance reproduces the data well and gives the magnitude of p–d exchange interaction as $|N_0\beta| = 1.5 \pm 0.2$ (Omiya *et al*., 2000), which compares favorably with that determined by photoemission experiments, $N_0\beta = -1.2\,\mathrm{eV}$ (Okabayashi *et al*., 1998).

At low temperatures, the negative MR extends to rather high H, where magnetic spins are fully ordered ferromagnetically according to the anomalous Hall effect response. This cannot be accounted for by the suppression of spin-disorder scattering. Here, one should note that the giant splitting of the valence band makes both spin-disorder and spin-orbit scattering ineffective. Under such conditions, negative MR due to weak localization can show up at low temperatures, where phase breaking scattering ceases to operate. The weak localization MR is expressed as

$$\frac{\Delta\rho}{\rho} \sim -\frac{\Delta\sigma}{\sigma} = -\frac{n_v e^2 C_0 \rho (eB/\hbar)^{1/2}}{(2\pi^2\hbar)} \qquad (2)$$

where $C_0 \sim 0.605$, ρ is resistivity, σ is conductivity, $\hbar$ is the reduced Planck constant, and $1/2 \leq n_v \leq 2$, depending on whether one or all four hole subbands (spin-split bands of light and heavy holes) contribute to the charge transport (Kawabata, 1980). The fitting to equation (2) with n_v as a fitting parameter reproduces the data at 2 K quite well for samples under compressive as well as for those under tensile strain (Matsukura *et al*., 2004). Metal–insulator transition (MIT)-associated feature can also be observed for insulating (Ga,Mn)As, which shows an anisotropic hopping conduction with 2 orders of magnitude difference between the resistivity along [110] and [−110] directions below 1 K (Katsumoto *et al*., 1998).

The Baukhausen noise caused by the scattering due to the existence of magnetic domain walls (DWs) has been observed in the resistance measurement (Hayashi *et al*., 2000). Magnetic DW is known to contribute to the electrical resistance. The domain wall resistance (DWR) of a single DW has been measured for (Ga,Mn)As; a negative sign of DWR was reported for (Ga,Mn)As with in-plane easy axis, and a positive was reported for that with perpendicular easy axis (Tang *et al*., 2004; Chiba *et al*., 2006). The former negative DWR may be explained by the destruction

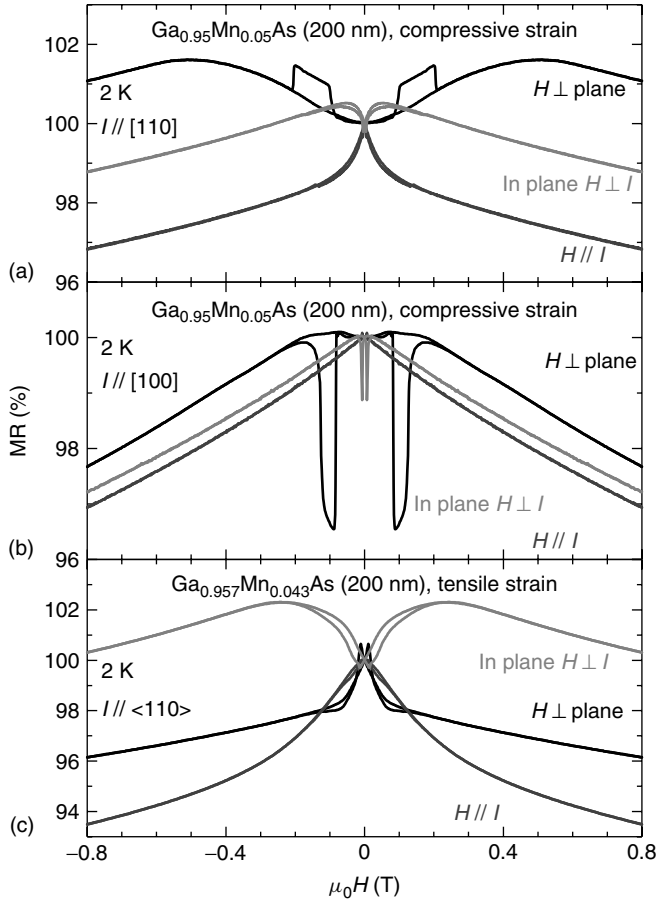

Figure 4. AMR of (Ga,Mn)As with compressive (a and b) and tensile strain (c). The current direction is (a) along [110], (b) [100], and (c) ⟨110⟩. (Reproduced from F. Matsukura *et al*., 2001, with permission from Elsevier. © 2001.)

of quantum coherence of electrons at the DW (Tatara and Fukuyama, 1997) and/or by the AMR contribution. The latter positive DWR can be decomposed into the extrinsic and intrinsic DWR components. Numerical calculation can explain well, as shown in Figure 5, that the extrinsic DWR is dominated by the zigzag current due to the alternating polarity of the anomalous Hall effect at DW (Partin, Karnezos, de Menezes and Berger, 1974), and that the remaining DWR is shown to be of the same order of the resistance due to the mistracking of the carrier spins inside DW (Chiba *et al*., 2006; Levy and Zhang, 1997).

The spin polarization of holes in (Ga,Mn)As has been measured by the Andreev reflection to be as high as ∼80% and similar effective polarization determined from the magnitude of tunneling magnetoresistance (TMR) (290%) at low temperatures (Barden *et al*., 2003; Chiba, Matsukura and Ohno, 2004). These results are consistent with the theoretical calculations of (Ga,Mn)As (Ogawa, Shirai, Suzuki and Kitagawa, 1999; Dietl, Ohno and Matsukura, 2001).

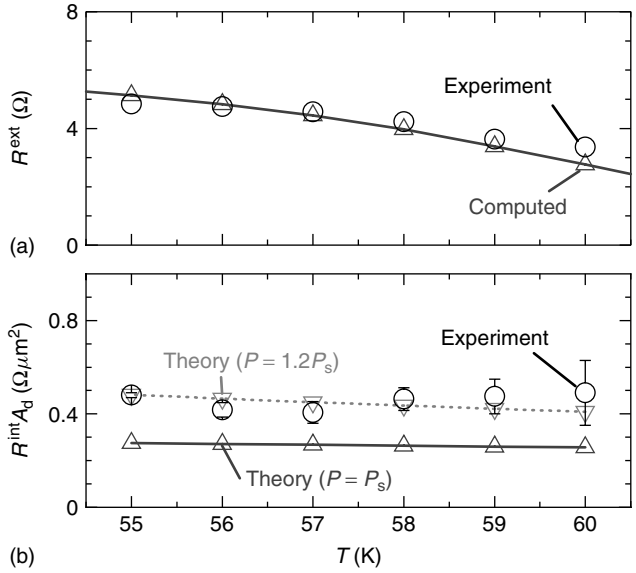

Figure 5. The temperature dependence of experimental and numerical DW resistance per one DW for (a) extrinsic and (b) intrinsic components. (After Chiba *et al*. (2006).)

3.3 Magnetic anisotropy

The direction as well as the magnitude of the magnetocrystalline anisotropy of (Ga,Mn)As can be tuned by the direction and the magnitude of the lattice strain as well as p. A number of methods have been employed to determine the magnetic anisotropy of (Ga,Mn)As, for example, magnetization, ac susceptibility, ferromagnetic resonance (FMR), anomalous Hall effect, planar Hall effect, AMR, TMR, and magneto-optical microscope measurements (Sawicki *et al*., 2004, 2005; Wang *et al*., 2005b; Liu, Sasaki and Furdyna, 2003; Liu, Lim, Dobrowolska and Furdyna, 2005; Shen *et al*., 1997a; Tang, Kawakami, Awschalom and Roukes, 2003; Hamaya *et al*., 2003, 2004; Uemura, Sone, Matsuda and Yamamoto, 2005; Welp *et al*., 2003). The layers under compressive strain, (Ga,Mn)As on GaAs, usually show in-plane magnetic easy axis, while the layers under tensile strain, like (Ga,Mn)As on (In,Ga)As, show magnetic easy axis perpendicular to the plane (Shen *et al*., 1997a). The single ion anisotropy of Mn in GaAs is confirmed to be too small to explain this sizable magnetic anisotropy (Fedorych, Hankiewicz, Wilamowski and Sadowski, 2002). The origin of this strain-dependent magnetic anisotropy is explained in terms of the warped anisotropic valence band due to the spin–orbit interaction and the lattice stain in the framework of the p–d Zener model, which also predicts that the magnetic anisotropy is p dependent (Dietl *et al*., 2000; Dietl, Ohno and Matsukura, 2001; Abolfath, Jungwirth, Brum and MacDonald, 2001). The p-dependent part has later been confirmed experimentally in (Al,Ga,Mn)As, where Al reduces

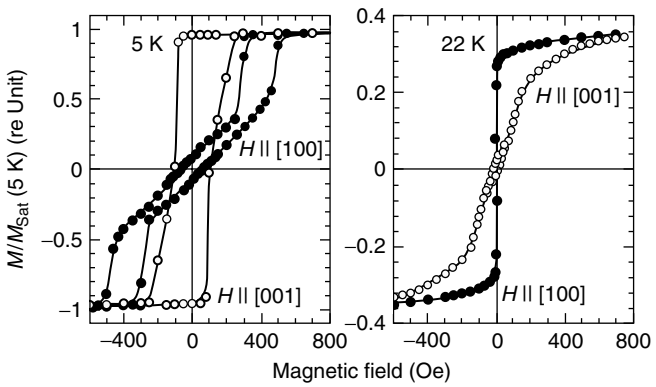

Figure 6. H dependence of magnetization normalized by its saturation value at 5 K for two directions of the film in respect to H (closed symbols and open symbols are for in-plane and perpendicular H respectively) at two temperatures. (After Sawicki *et al.* (2004).)

hole concentration, and in (Ga,Mn)As with a high degree of compensation. There the direction of magnetic easy axis is temperature dependent and changes its direction from in plane to perpendicular as temperature decreases, as shown in Figure 6 (Takamura, Matsukura, Chiba and Ohno, 2002; Sawicki *et al.*, 2003, 2004), in accordance with what is predicted for the low p case by the p–d Zener model. Furthermore, (Ga,Mn)As shows fourfold in-plane easy axis along ⟨100⟩ and uniaxial easy axis along [110] or [−110] (Hayashi *et al.*, 2000; Sawicki *et al.*, 2005). The in-plane uniaxial anisotropy cannot be explained by the p–d Zener model, without assuming the presence of shear strain, which has not yet been confirmed experimentally, and its exact origin remains unclear. It has been suggested that it may be related to the anisotropic (1×2) surface reconstruction during MBE growth, the lack of top–bottom symmetry in epilayers, or the existence of a trigonal distortion (Welp *et al.*, 2003; Sawicki *et al.*, 2004, 2005).

The magnetic overlayers on (Ga,Mn)As can induce the additional anisotropy to (Ga,Mn)As. The pinning of the M direction or exchange biasing of (Ga,Mn)As is shown to be possible with overlayers of spin glass (Zn,Mn)Se and antiferromagnetic MnO (Liu, Sasaki and Furdyna, 2001; Fid *et al.*, 2004).

3.4 Low-temperature annealing

Low-temperature annealing (Hayashi, Hashimoto, Katsumoto and Iye, 2001) is now a standard process to improve the quality of (Ga,Mn)As. An appropriate LT-annealing process increases the electrical conductivity due to the increase in p and at the same time increases T_C. LT annealing allows us to measure the correlation between the electrical conductivity and T_C using a set of samples cleaved from the same wafer, where a monotonic positive dependence of T_C on the conductivity was observed. This is one of the evidences of the hole-induced ferromagnetism (Edmonds *et al.*, 2002b). Initially, the effect was suspected to be due to As antisites, which act as a double donor in GaAs. A series of studies established that the annealing effect is coming from reducing the number of Mn_I. As shown by the EXAFS and the channeling measurements (Shioda, Ando, Hayashi and Tanaka, 1998; Yu *et al.*, 2002a), Mn occupies two distinct positions, Ga and interstitial sites, in zinc-blende host GaAs lattice. Mn_{Ga} acts as a single acceptor, while Mn_I as a double donor. When Mn can be considered the only dopant, p can be expressed by the concentrations of Mn_{Ga} and Mn_I, as $p = [Mn_{Ga}] - 2[Mn_I]$. This relationship was confirmed experimentally by a combination of channeling and ECV measurements, as shown in Figure 7 (Wojtowicz *et al.*, 2004). In addition, Mn_{Ga} and Mn_I can form antiferromagnetic pairs, in which the Mn moments are cancelled. Thus, if all Mn_I form a pair with Mn_{Ga}, the effective Mn composition contributing to ferromagnetic order is the difference in the compositions of Mn_{Ga} and Mn_I, $x_{eff} = ([Mn_{Ga}] - [Mn_I])/N_0$, where N_0 is the density of the cation sites. If one assumes this relation, the magnetization data have been shown to yield $\sim 5\,\mu_B$ per Mn atom, consistent with the expected value for Mn^{2+}, in a wide range of x from 0.02 to 0.09, as shown in Figure 8 (Wang *et al.*,

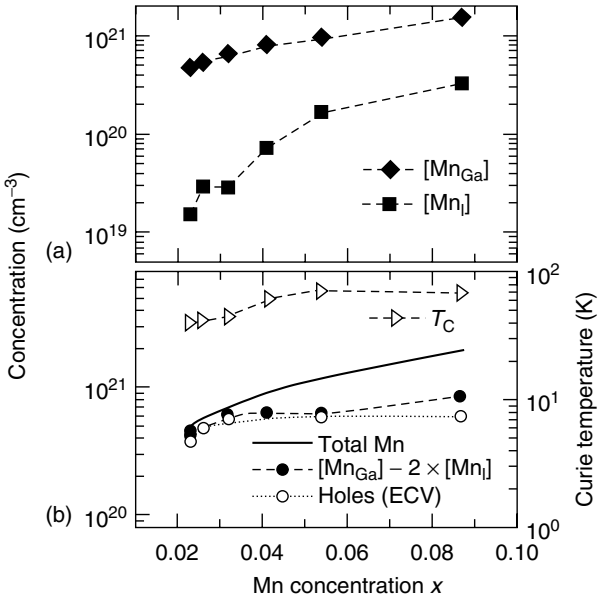

Figure 7. (a) The concentration of Mn_{Ga} and Mn_I versus x. (b) The x dependence of concentration of uncompensated Mn_{Ga}, $[Mn_{Ga}]-2[Mn_I]$ and p measured by ECV. T_C and concentration of total Mn concentration, $Mn_{Ga} + Mn_I$, are also plotted. (Reproduced from T. Wojtowicz *et al.*, 2004, with permission from Elsevier. © 2004.)

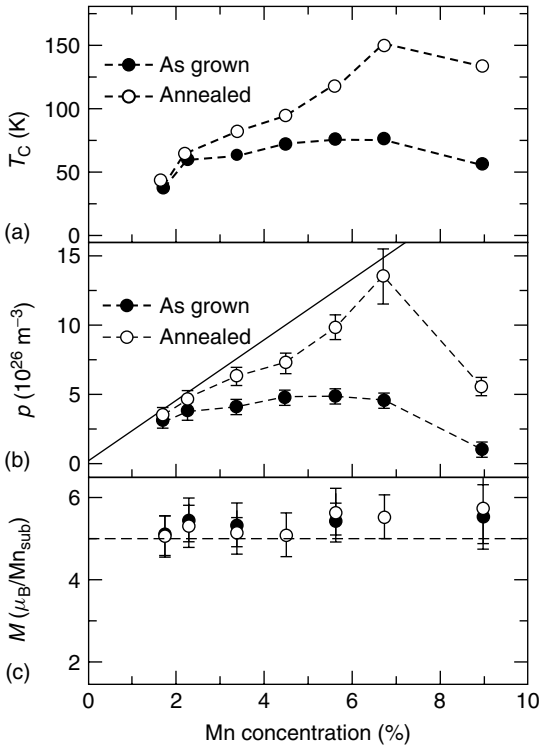

Figure 8. (a) T_C (b) p dependence on x for as-grown and annealed samples. The linear solid line in (c) presents the p expected without compensation. (c) Estimated magnetic moment per uncoupled Mn_{Ga} with the assumption of the antiferromagnetic coupling of Mn_{Ga} and Mn_I. (Reproduced from K.Y. Wang *et al*., 2004, with permission from the American Institute of Physics. © 2004.)

2004). The good agreement for both as-grown and annealed samples seen in Figure 8 also indicates that the increase in T_C after LT annealing is a combined result of increased p and x_{eff} due to the reduction of $[Mn_I]$.

The self-compensation of Mn is enhanced at higher x, and results in almost the same p for as-grown (Ga,Mn)As with x greater than 0.02, but overcompensation has never been observed. Thus, the self-compensation is believed to be related to the Fermi level pinning effect (Walukiewicz, 1988). This suggests that once the Fermi level reaches a certain position in the valence band, it becomes energetically favorable to form Mn_I as a counterdopant (Yu *et al*., 2003).

The effect of the LT annealing is strongly structure dependent. The increase in T_C by LT annealing is greater for thinner (Ga,Mn)As and is observed for the (Ga,Mn)As layers with bare surface, that is, LT-annealing effect is suppressed with a cap GaAs layer with thickness beyond 10 monolayers (Chiba, Takamura, Matsukura and Ohno, 2003; Stone *et al*., 2003). These results indicate that diffusion to and/or from the surface plays a role in the LT-annealing process. The surface Mn Auger signal increases after annealing, indicating that Mn out diffuses and accumulates at the surface during the process (Edmonds *et al*., 2004). This is shown to be modeled by a one-dimensional out-diffusion model (Edmonds *et al*., 2004). It has also been suggested that the diffusion of Mn to the substrate side may be limited electrostatically by the formation of a p–n junction by Mn_I and Mn_{Ga}. According to this scenario, Mn_I becomes electrically inactive at the surface and is trapped as a result of oxidation or some other unknown reasons; thus, the LT annealing is expected to depend on the atmosphere and an additional layer on the surface. More efficient LT-annealing effects are observed for (Ga,Mn)As annealed in O_2 and (Ga,Mn)As with an amorphous As capping layer, where the formation of Mn–O and Mn–As at the surface may work to reduce the number of Mn_I (Malfait *et al*., 2005; Adell *et al*., 2005). Another important effect is that the LT annealing can produce a more homogeneous magnetization depth profile than that of an as-grown sample, which was confirmed by polarized neutron reflectometry measurements (Kirby *et al*., 2004).

Postgrowth hydrogenation of (Ga,Mn)As results in reduction of p and is shown to lead to suppression of ferromagnetism (Gonnenwein *et al*., 2004).

3.5 Magneto-optical properties

Magneto-optical properties have been studied to elucidate the origin of ferromagnetism of (Ga,Mn)As because they can probe the spin-split band structure induced by the sp–d exchange interaction. When the origin of the ferromagnetism is intrinsic, a large magneto-optical response should be observed at the critical points of the host zinc-blende semiconductors. This is indeed the case for (Ga,Mn)As, and a large Faraday rotation and magnetic circular dichroism (MCD) signals have been observed at critical points E_0 and E_1, whose H dependence traces the magnetization curves well (Kuroiwa *et al*., 1998; Ando, Hayashi, Tanaka and Twardowski, 1998; Beshoten *et al*., 1999). The sign of these signals is opposite to that of most of the II–VI DMSs with a negative p–d exchange. This can be explained by a spin-dependent Burnstein–Moss shift caused by hole redistribution that is taken into consideration (Szczytko *et al*., 1999; Dietl, Ohno and Matsukura, 2001).

4 HETEROSTRUCTURES AND DEVICE STRUCTURES

In order to show new spin-dependent phenomena and to explore the possibility of their future device application, a

number of ferromagnetic semiconductor-based heterostructures are now being investigated experimentally as well as theoretically. In this section, we review the results of heterostructures and device structures, which exhibit new phenomena that are not available in existing semiconductor devices.

4.1 Control of magnetism and magnetization reversal by external means

Since the ferromagnetism in (Ga,Mn)As and (In,Mn)As is stabilized by the presence of holes, it is expected that one can switch magnetic phases without changing the temperature by electrical means, which controls the value of p. This has been shown to be possible using a metal–insulator–semiconductor field-effect transistor (MISFET) structure with a thin (In,Mn)As layer ($\leq$5 nm) as a semiconductor channel (Ohno *et al*., 2000). The (In,Mn)As layers are grown on a GaAs substrate with a thick (Al,Ga)Sb buffer layer to relax the large lattice mismatch between (In,Mn)As and GaAs. The devices have a Hall-bar shape, in order to probe the magnetization through the anomalous Hall effect. Since the channel is p-type, the application of positive (negative) gate electric field E_G decreases (increases) p; for the structure under discussion $|E_G| = 1.5\,\mathrm{MV\,cm^{-1}}$ changes several percents of total p. In the vicinity of T_C, the magnetization curves show a more square shape under negative E_G, indicating an enhanced ferromagnetic order, while they show a paramagnetic-like response under positive E_G, as shown in Figure 9. This reversible change of T_C by $E_G = \pm 1.5\,\mathrm{MV\,cm^{-1}}$ determined using the Arrott plots can be as large as 4 K for 4-nm-thick (In,Mn)As (Chiba, Yamanouchi, Matsukura and Ohno, 2003). Control of T_C by electrical means is also a proof that the ferromagnetism in this material is carrier induced.

Another important effect of E_G is the change of the coercive force H_C below T_C; larger (smaller) H_C for negative (positive) E_G. By using this phenomenon, a new scheme of electrical magnetization reversal, electric-field-assisted magnetization reversal, has been demonstrated as follows: After saturation of magnetization at positive H under $E_G = -1.5\,\mathrm{MV\,cm^{-1}}$, one reduces H through zero to a small negative H but still less than the coercive force, H_C. Then, E_G is switched to zero, which reduces $|H_C|$ below $|H|$ and switching takes place (Chiba, Yamanouchi, Matsukura and Ohno, 2003).

Although there has only been limited success on (Ga,Mn)As (Chiba *et al*., 2003), recent progress in low-temperature deposition of high-quality insulators made it possible to observe a similar electrical modulation of T_C and H_C in (Ga,Mn)As (Chiba, Matsukura and Ohno, 2006a).

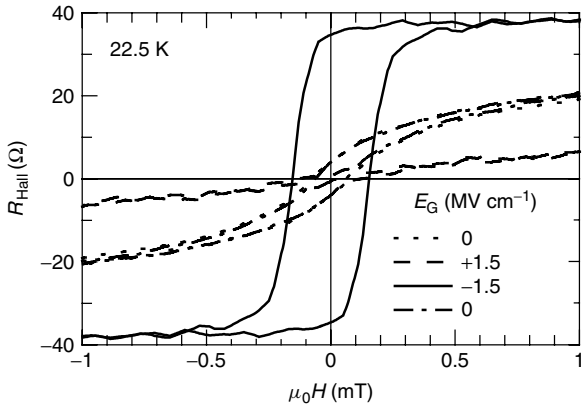

Figure 9. R_{Hall} versus $\mu_0 H$ under three different E_G. R_{Hall} is measured at $E_G = 0$ before and after the application of E_G. (Reproduced from Ohno *et al*., 2000, with permission from Nature Publishing Group. © 2000.)

The change in magnetic properties and H_C in (In,Mn)As has also been demonstrated by light irradiation, where the photogenerated carriers play a role (Koshihara *et al*., 1997; Oiwa, Słupinski and Munekata, 2001; Kanamura *et al*., 2002; Liu *et al*., 2004). Owing to the existence of persistent photoconductivity, the phenomena are occasionally not isothermal: in which case one needs to warm up the sample to return to the original state. The magnetization enhancement of (Ga,Mn)As by circularly polarized light illumination has also been observed for (Ga,Mn)As and Mn δ-doped GaAs (Oiwa *et al*., 2002; Nazmul, Kobayashi, Sugahara and Tanaka, 2004).

4.2 Tunneling magnetoresistance and current-induced magnetization switching

Magnetic tunnel junctions (MTJs) based on (Ga,Mn)As, such as (Ga,Mn)As/AlAs/(Ga,Mn)As and (Ga,Mn)As/GaAs/(Ga,Mn)As, show TMR (Hayashi, Shimada, Shimizu and Tanaka, 1999; Chiba *et al*., 2000), where parallel and antiparallel configurations of the magnetization of the two (Ga,Mn)As layers result in low- and high-resistance (R_P and R_{AP}) states, just as metal MTJs. Note that GaAs acts as a barrier layer for holes in (Ga,Mn)As (Ohno, Arata, Matsukura and Ohno, 2002). The highest TMR ratios [$= (R_{AP} - R_P)/R_P$] so far are 75 and 290% for AlAs and GaAs intermediate barrier layer, as shown in Figure 10, respectively. The latter corresponds to effective carrier spin polarization $P = 77\%$, according to the Julliere's formula, TMR ratio $= 2P^2/(1-P^2)$ (Tanaka and Higo, 2001; Chiba, Matsukura and Ohno, 2004).

In submicron (Ga,Mn)As MTJs, current-induced magnetization switching (CIMS) has been observed (Chiba *et al*., 2004; Elsen *et al*., 2006). On the R_P state, the current pulse, injected from the thicker to thinner (Ga,Mn)As, induces

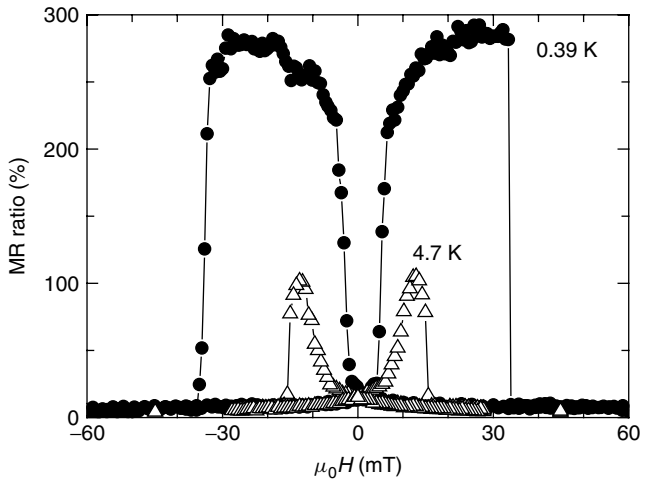

Figure 10. Tunneling magnetoresistance of (Ga,Mn)As/GaAs/(Ga,Mn)As under H // [100] measured at low temperatures. (Reproduced from D. Chiba *et al*., 2004a, with permission from Elsevier. © 2004a.)

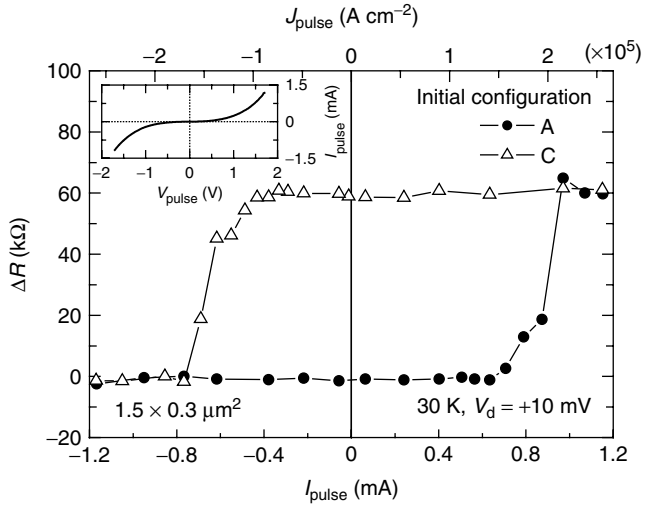

Figure 11. The magnitude of the current pulse dependence ΔR, which is the difference of the resistance after current pulse injection and R_P of $1.5 \times 0.3\,\mu m^2$ device at 30 K. Closed circles show ΔR for initial configuration A (parallel M) and open triangles for initial configuration C (antiparallel M). The inset shows current–voltage characteristic of the device. (After Chiba *et al*. (2004).)

the magnetization reversal in the thinner (Ga,Mn)As, and results in the R_{AP} state. The opposite sign of current induces the magnetization reversal again in the thinner (Ga,Mn)As layer and results in the R_P state, as shown in Figure 11. The critical current density J_C for switching is of the order of $10^4 \sim 10^5\,A\,cm^{-2}$. The CIMS in (Ga,Mn)As-based MTJ can be explained qualitatively by the Slonczewski's spin-transfer torque model (Slonczewski, 1996), although the model predicts an order of magnitude greater J_C than the observed one. The large bias dependence of TMR ratio and its possible role in the CIMS process is not understood at the moment, along with the nature of the possible incoherent switching process, such as the formation of domain structure (Chiba *et al*., 2004; Chiba, Matsukura and Ohno, 2006b; Chiba, Kita, Matsukura and Ohno, 2006; Elsen *et al*., 2006; Moriya, Hamaya, Oiwa and Munekata, 2004).

A very large tunnel anisotropic magnetoresistance (TAMR) up to 150 000% has been reported in (Ga,Mn)As-based MTJs in vertical and lateral device structures (Rüster *et al*., 2003, 2005; Giddings *et al*., 2005). Although it needs further work to firmly establish the origin of TAMR (Saito, Yuasa and Ando, 2005), it has been attributed to anisotropic valence band structure induced by the spin–orbit interaction and lattice strain in combination with the MIT.

4.3 Current-induced domain wall motion

By the application of a current pulse across the DW, it has been found that the position of DW can electrically be manipulated in the absence of a magnetic field (Yamanouchi, Chiba, Matsukura and Ohno, 2004). The electrical channel made from (Ga,Mn)As used in the experiment has magnetic easy axis perpendicular to the surface by inserting the (In,Ga)As or (In,Al)As buffer layer. This easy axis direction is not only useful in monitoring the DW position through the anomalous Hall effect and by the magneto-optical Kerr effect (MOKE) microscope but also essential in observing the effect, as discussed in the following text. The DW switching was observed for the channel with three regions with different thickness, where the thinnest region was set to the center of the channel. Note that this stepped structure allows patterning H_C due to slight nonuniformity in the film and each step acts as a confinement potential for DW. The DW position was initialized to one of the stepped boundaries of the thinnest region by H. After setting $H = 0$, a current pulse of $10^5\,A\,cm^{-2}$ for 100 ms at 80 K (T_C of this film is 90 K) was applied. Both the anomalous Hall signals and MOKE images indicated that the DW moved to the other step boundary, in the direction opposite to the current direction. The application of a subsequent current pulse in the opposite direction switched back the DW to its initial position. The DW was confined by the two stepped boundaries, as expected from the increase in the DW energy in the adjacent layers.

The temperature dependence as well as the current density (j) dependence of the DW velocity have been measured systematically using a 5-μm-wide (Ga,Mn)As channel with a single step (Yamanouchi *et al*., 2006). The DW initially at the step was moved by the current pulse, and the DW swept area was monitored by MOKE to obtain the effective DW speed, v_{eff}, from the effective DW displacement, the

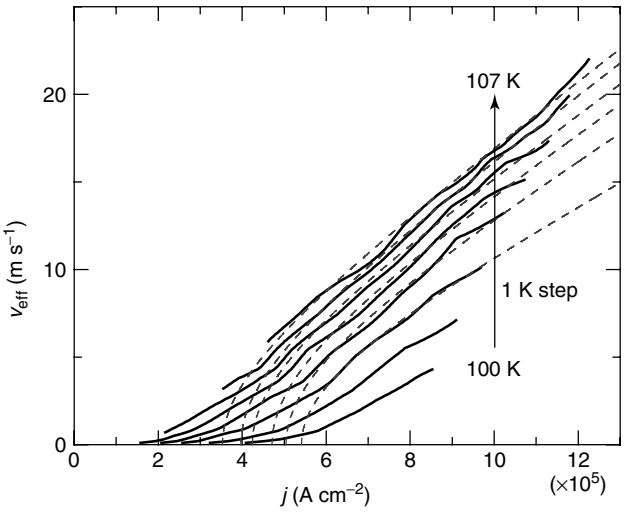

Figure 12. DW velocity as a function of current density at various device temperatures. The thin broken lines show fitted theoretical dependence of velocity on current density. (After Yamanouchi *et al.* (2006).)

value of the area being divided by the width, for a given pulse width; the displacement was linearly dependent on the pulse width. The change in the device temperature by the Joule heating was calibrated by measuring the device resistance during the pulse application and compared with the temperature dependence of the device resistance. The j dependence of $v_{\rm eff}$ at a fixed temperature showed that there are at least two regimes separated by a critical current density $j_{\rm C}$, which is of a few hundreds of thousands of amperes per centimeter square, as shown in Figure 12. Beyond $j_{\rm C}$, $v_{\rm eff}$ increased linearly with j, while below $j_{\rm C}$ the DW velocity was slow and its functional form much more involved. The linear dependence of $v_{\rm eff}$ above $j_{\rm C}$ and the value of $j_{\rm C}$ were found to be explained quantitatively well, including the direction of the movement by the spin-transfer mechanism with an intrinsic DW pinning (Tatara and Kohno, 2004). The j dependence of $v_{\rm eff}$ below $j_{\rm C}$ obeys an empirical scaling law, suggesting the existence of current-induced DW creep (Lemerle *et al.*, 1998).

We note that in metallic structures this intrinsic $j_{\rm C}$ is too high and is beyond one's reach, and thus the velocity versus current density curves are the first of this kind determined in ferromagnetic materials. Even with (Ga,Mn)As, the in-plane anisotropy is expected to result in an order of magnitude higher $j_{\rm C}$ due to magnetocrystalline anisotropy.

4.4 Spin injection into nonmagnetic semiconductors

Owing to spontaneous magnetization, spontaneous spin polarization of carriers exists in ferromagnetic semiconductors below $T_{\rm C}$. Thus, these materials can be used as a spin-polarized carrier emitter into the nonmagnetic structures under the absence of magnetic field. Spin injection from (Ga,Mn)As to nonmagnetic GaAs has been demonstrated by devices combining a GaAs-based nonmagnetic light-emitting diode (LED) structure as spin-polarized carrier detectors (Ohno *et al.*, 1999). In the electroluminescence (EL) measurements, partial spin polarization of injected carriers from (Ga,Mn)As through GaAs to (In,Ga)As quantum well, where they recombine with unpolarized electrons from backside n-type GaAs, was detected in the form of circular polarization of the EL signals. Injection of spin-polarized electrons has also been demonstrated successfully using an Esaki tunnel diode structure as a spin emitter, where spin-polarized holes in the valence band of (Ga,Mn)As are injected into the conduction band of an adjacent n-GaAs by interband tunneling (Kohda *et al.*, 2001; Jonston-Halperin *et al.*, 2002; Van Dorpe *et al.*, 2004). By the use of a three-terminal device structure to control bias voltages of Esaki diode and LED independently, as shown in Figure 13, the efficiency of the spin injection to LED has been measured as a function of the bias voltage. EL polarization up to 32.4% was obtained, suggesting that the injected electrons have high spin polarization of over 85% (Kohda *et al.*, 2006).

5 TOWARD HIGH CURIE TEMPERATURE FERROMAGNETIC SEMICONDUCTORS

5.1 Other ferromagnetic semiconductors

Following theoretical predictions (Dietl *et al.*, 2000; Dietl, Ohno and Matsukura, 2001; Sato and Katayama-Yoshida, 2000), a worldwide effort for synthesizing ferromagnetic semiconductors with high $T_{\rm C}$ is now underway. Ferromagnetic semiconductors based on wide-gap semiconductors such as GaN and ZnO have extensively been investigated (Pearton *et al.*, 2003), as the chemical trend pointed out by the theoretical studies indicates that this is the right direction to be followed. There are many encouraging reports on the observation of room-temperature ferromagnetism in wide-gap materials doped with transition metals or rare earths. Some of them have shown to be able to see a correlation between magnetization and MCD signals at semiconductor critical points and/or the anomalous Hall effect (Saito, Zayets, Yamagata and Ando, 2003; Toyosaki *et al.*, 2004). In order to firmly establish whether the observed ferromagnetic order is intrinsic and is what one is looking for, it is now becoming increasingly clear that one needs to do a series of measurements to carefully rule out the possibilities

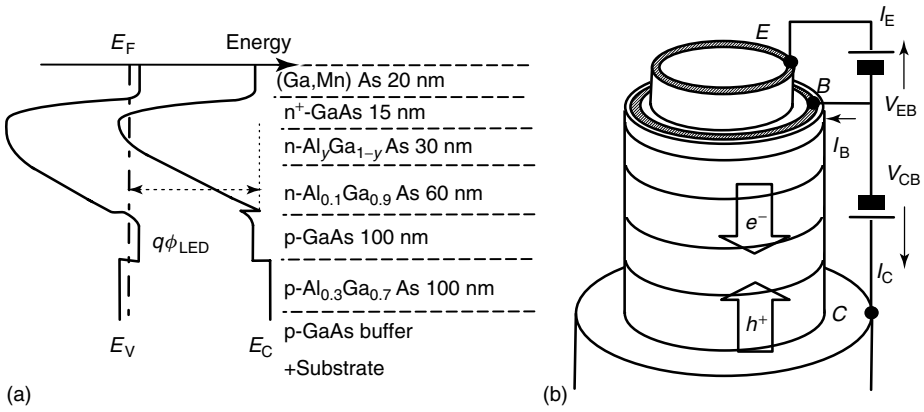

Figure 13. (a) The schematic band diagram and (b) the three-terminal device of Esaki diode on LED. (Reproduced from M. Kohda *et al*., 2006, with permission from the American Institute of Physics. © 2006.)

of having magnetic precipitates (Dietl, this volume). These precipitates can be of the same crystal structure stabilized by the host lattice, meaning that there is no bulk counterpart. They may have an elongated structure (Singh *et al*., 2005) with a high blocking temperature, thereby exhibiting hysteresis and anisotropy. They can even be antiferromagnetic clusters with uncompensated spins.

In an effort to integrate room-temperature ferromagnetic materials to nonmagnetic semiconductor monolithically, metal materials that have the same crystal structure as that of the host semiconductor have also been investigated. So far, single-crystal zinc-blende CrAs and CrSb were grown by MBE and were confirmed to show ferromagnetism over 400 K (Akinaga, Manago and Shirai, 2000; Zhao *et al*., 2001). Theoretical calculation predicts that these materials have half-metallic band structure (Shirai, 2003).

5.2 Perspective and remarks

According to the p–d Zener model, higher values of x_{eff} and p are keys to increase T_C of (Ga,Mn)As, and more material science is needed in this direction, where challenges are the solubility limit and self-compensation. In order to overcome these obstacles, there are several proposals, such as codoping of donors to reduce the number of Mn_I, the optimization of annealing condition, and the use of high-index substrate to increase Mn incorporation efficiency (Yu *et al*., 2003; Wang *et al*., 2005c). The artificial structure to increase local Mn composition and hole concentration simultaneously is another promising direction to be followed; T_C of 250 K was observed in a Mn δ-doped structure with modulation doping to increase hole concentration (Nazmul *et al*., 2005).

Synthesis of ferromagnetic semiconductors based on wide-band gap semiconductors, which are expected to have greater p–d exchange, is another method that was adopted to increase T_C. Although there are a number of encouraging reports, recent theoretical work has pointed out the presence of attractive chemical interactions between magnetic ions and the possibility of having spinodal decomposition (Sato, Katayama-Yoshida and Dederichs, 2005; Fukushima, Sato, Katayama-Yoshida and Dederichs, 2006). It has also been argued that high x is necessary due to the lack of long-range exchange interaction among magnetic spins in these materials (Bergvist *et al*., 2004; Sato, Scheika, Dederichs and Katayama-Yoshida, 2004).

If one is searching for carrier-induced ferromagnetism, then the dependence of magnetic properties on carrier type and its concentration is one of the critical indicators of intrinsic ferromagnetism. The existing theories imply that T_C depends on x, for example, $T_C \propto x$ by the p–d Zener model and $T_C \propto x^{1/2}$ by the double-exchange model (Dietl *et al*., 2000; Dietl, Ohno and Matsukura, 2001; Sato, Dederics and Katayama-Yoshida, 2003), and thus the dependence of magnetic properties on x conveys important information. The existence of the correlation among magnetization, magneto-optical, and magnetotransport properties is one of the necessary conditions of intrinsic ferromagnetism, although large magneto-optical and magnetotransport phenomena for the material with small spin–orbit interaction are not expected. The measurement of carrier spin polarization includes typical properties for ferromagnetic semiconductors reflecting spin-split subband states induced by sp–d exchange interaction (Barden *et al*., 2003; Chiba, Matsukura and Ohno, 2004). The controllability of magnetism by external means is important to confirm the intrinsic ferromagnetism and to demonstrate the possibility in applications (Ohno *et al*., 2000).

Finally, we point out that even if the ferromagnetism-like response has turned out to be originating from precipitates, having ferromagnetic-like inclusion seamlessly integrated into a host semiconductor can be useful depending on what we want to do with semiconductor-magnetism integration.

6 SUMMARY

Ferromagnetic semiconductors are providing an excellent test bench for exploring spin-dependent phenomena in semiconducting materials and to demonstrate new phenomena, ranging from electric-field manipulation of ferromagnetism through CIMS and current-induced DW motion to spin injection in an integrated semiconductor structure for possible spintronic applications, where both charge and spins play critical roles. Directions as well as precautions to be taken for pursuing high transition temperature ferromagnetic semiconductors are also discussed.

Diluted Ferromagnetic Semiconductors – Theoretical Aspects

Tomasz Dietl
Institute of Physics and Warsaw University, Warszawa, Poland

1 INTRODUCTION

The family of diluted magnetic semiconductors (DMS) encompasses standard semiconductors, in which a sizable portion of atoms is substituted by such elements, which produce localized magnetic moments in the semiconductor matrix. Usually, magnetic moments originate from 3d or 4f open shells of transition metals (TMs) or rare earths (REs) (lanthanides), respectively, so that typical examples of DMS are $Cd_{1-x}Co_xSe$, $Ga_{1-x}Mn_xAs$, $Pb_{1-x}Eu_xTe$ and, in a sense, Si:Er. A strong spin-dependent coupling between the band and localized states accounts for outstanding properties of DMS. This coupling gives rise to spin-disorder scattering, giant spin splittings of the electronic states, formation of magnetic polarons, and strong indirect exchange interactions between the magnetic moments, the latter leading to collective spin glass, antiferromagnetic, or ferromagnetic spin ordering. Owing to the possibility of controlling and probing magnetic properties by the electronic subsystem or vice versa, DMS have been successfully employed to address a number of important questions concerning the nature of various spin effects in various environments and at various length and timescales. At the same time, DMS exhibit a strong sensitivity to the magnetic field and temperature as well as constitute important media for generation of spin currents and for manipulation of localized or itinerant spins by, for example, strain, light, electrostatic, or ferromagnetic gates. These properties, complementary to both nonmagnetic semiconductors and magnetic metals, open doors for application of DMS as functional materials in spintronic devices.

Extensive studies of DMS started in 1970s, particularly in the group of Robert R. Gałązka in Warsaw, when appropriately purified Mn was employed to grow bulk II–VI Mn-based alloys by various modifications of the Bridgman method (Gałązka, 1978). Comparing to magnetic semiconductors, such as Eu chalcogenides (e.g., EuS) and Cr spinels (e.g., $CdCr_2Se_4$) investigated earlier (Nagaev, 1983), DMS exhibited smaller defect concentrations and were easier to dope by shallow impurities. Accordingly, it was possible to examine their properties by powerful magneto-optical and magnetotransport techniques (Dietl, 1994; Gałązka, 1978, 1981; Furdyna and Kossut, 1988; Awschalom and Samarth, 2002). Since, in contrast to magnetic semiconductors, neither narrow magnetic bands nor long-range magnetic ordering affected low-energy excitations, DMS were named semimagnetic semiconductors. More recently, research on DMS have been extended toward materials containing magnetic elements other than Mn as well as to III–VI, IV–VI (Bauer, Pascher and Zawadzki, 1992), and III–V (Matsukura,

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

Ohno and Dietl, 2002) compounds as well as group IV elemental semiconductors and various oxides (Prellier, Fouchet and Mercey, 2003). In consequence, a variety of novel phenomena had been discovered, including effects associated with narrow bands and magnetic phase transformations, making the borderline between properties of DMS and magnetic semiconductors more and more elusive.

A rapid progress of DMS research in 1990s stemmed, to a large extent, from the development of methods of crystal growth far from thermal equilibrium, primarily by molecular-beam epitaxy (MBE) but also by laser ablation. These methods have made it possible to obtain DMS with the content of the magnetic constituent beyond thermal equilibrium solubility limits (Ohno, 1998). Similarly, the doping during MBE process allows one to increase substantially the electrical activity of shallow impurities (Haury *et al*., 1997; Ferrand *et al*., 2001). In the case of III–V DMS (Matsukura, Ohno and Dietl, 2002), in which divalent magnetic atoms supply both spins and holes, the use of the low-temperature MBE provides thin films of, for example, $Ga_{1-x}Mn_xAs$ with x up to 0.08 and the hole concentration approaching $10^{21}\,cm^{-3}$, in which ferromagnetic ordering is observed up to 170 K (Wang *et al*., 2005). Remarkably, MBE and processes of nanostructure fabrication, make it possible to add magnetism to the physics of semiconductor quantum structures. Particularly important are DMS, in which ferromagnetic ordering was discovered, as discussed here and in the chapter **Ferromagnetic Semiconductors, Volume 5**.

Owing to novel functionalities (Ohno *et al*., 2000) and theoretical expectations (Dietl *et al*., 2000), an enormous activity has been directed to developing diluted ferromagnetic semiconductors sustaining ferromagnetic order up to high temperatures (Dietl, 2005; Liu, Yun and Morkoç, 2005) as well as to describing their properties theoretically (Jungwirth *et al*., 2006a). In fact, a ferromagnetic response, often persisting up to above room temperature, has been detected in a number of semiconductor and oxide thin layers doped with minute amount of magnetic ions (Dietl, 2005; Liu, Yun and Morkoç, 2005). As known, a highly sensitive SQUID magnetometer is necessary to detect the corresponding small signals, which are often inferior to those coming from typical remanent fields, sample holders, substrates, or residual magnetic nanoparticles originating from nominally nonmagnetic source materials or processing procedures. In rather rare cases, the ferromagnetic signal of DMS layers could univocally be assigned to precipitates of a known ferromagnetic or ferrimagnetic material. In few other cases, its magnitude has been greater than that evaluated from the nominal concentration of magnetic ions. More often, however, the ferromagnetic response of the layer coexists with paramagnetic characteristics, indicating that only a fraction of magnetic spins remains correlated at high temperatures.

A particularly important question that arises in this context is whether at the length scale appropriately greater than the mean distance between magnetic ions a spatially uniform ferromagnetic spin order is a real ground state of ferromagnetic DMS. Actually, the existence and the role of spatially nonuniform ferromagnetic spin order was an important theme in research on both magnetic semiconductors (Nagaev, 1983) and colossal magnetoresistance oxides (Dagotto, Hotta and Moreo, 2001). Nanoscale phase separation effects that were invoked to explained pertinent properties of those materials may *a priori* be even more relevant in ferromagnetic DMS, in which carrier correlation and electrostatic disorder associated with ionized impurities coexist with alloy disorder in the magnetic sublattice. We recall in this context that uncoupled nanoscale ferromagnetic regions of the volume V give rise to macroscopic ferromagnetic signatures, such as spontaneous magnetization and magnetic hysteresis, below the blocking temperature (e.g., Shinde *et al*., 2004), $T_B = KV/[k_B \ln(t_{lab}/\tau)]$, where K is the density of the magnetic anisotropy energy, and $\ln(t_{lab}/\tau) \approx 25$ for a typical ratio of a relevant spin-flip relaxation time τ to the time of hysteresis measurements, t_{lab}.

In the remaining part of this review, we focus on semiconductors which under doping with TM or RE become ferromagnetic but *remain* in the initial crystal structure or, in the other words, do not undergo any *crystallographic* phase separation. Therefore, the ferromagnetism of DMS considered here does not result simply from the precipitation of any known ferromagnetic or ferrimagnetic material. In particular, in the next section, we describe the present theoretical understanding of DMS showing *uniform* ferromagnetic order, such as (Ga,Mn)As or heavily doped p-(Zn,Mn)Te, in which interactions between randomly distributed magnetic ions are mediated by delocalized holes in the valence band. We then turn to DMS, in which a competition between long-range ferromagnetic and short-range antiferromagnetic interactions and/or the proximity to the localization boundary lead to the *electronic* nanoscale phase separation into areas of differing spin orders. Finally, we discuss, in some detail, systems exhibiting the *chemical* nanoscale phase separation into regions with a small and a large concentration of magnetic atoms, respectively.

2 SPATIALLY UNIFORM FERROMAGNETIC DMS

2.1 Overview

Since for decades, III–V semiconductor compounds have been applied as photonic and microwave devices, the discovery of ferromagnetism first in (In,Mn)As (Ohno *et al*.,

1992) and then in (Ga,Mn)As (Ohno *et al*., 1996) came as a landmark achievement. In these materials, substitutional divalent Mn ions provide localized spins and function as acceptor centers that provide holes which mediate the ferromagnetic coupling between the parent randomly distributed Mn spins (Dietl, Haury and Merle d'Aubigné, 1997; Matsukura, Ohno, Shen and Sugawara, 1998; Jungwirth, Atkinson, Lee and MacDonald, 1999). In another technologically important group of semiconductors, in II–VI compounds, the densities of spins and carriers can be controlled independently, similar to the case of IV–VI materials, in which hole-mediated ferromagnetism was discovered already in the 1980s (Story, Gałązka, Frankel and Wolff, 1986). Stimulated by the theoretical predictions (Dietl, Haury and Merle d'Aubigné, 1997), search for carrier-induced ferromagnetism in II–IV materials containing Mn was undertaken. Experimental studies conducted with the use of magneto-optical and magnetic methods led to the discovery of ferromagnetism in 2D (Haury *et al*., 1997) and 3D (Ferrand *et al*., 2001) II–VI Mn-based DMS doped by nitrogen acceptors.

Since magnetic properties are controlled by band holes, an appealing possibility is to influence the magnetic ordering isothermally, by light or by the electric field, which affect the carrier concentration in semiconductor quantum structures. Such tuning capabilities of the materials systems in question were put into the evidence in (In,Mn)As/(Al,Ga)Sb (Koshihara *et al*., 1997; Ohno *et al*., 2000) and modulation-doped p-(Cd,Mn)Te/(Cd,Mg,Zn)Te (Haury *et al*., 1997; Boukari *et al*., 2002) heterostructures. Actually, these findings can be quantitatively interpreted by considering the effect of the electric field or illumination on the hole density under stationary conditions and, therefore, on the Curie temperature in the relevant magnetic layers. Interestingly, according to experimental findings and theoretical modeling, photocarriers generated in II–VI systems by above barrier illumination destroy ferromagnetic order in the magnetic quantum well residing in an undoped (intrinsic) region of a p–i–p structure (Haury *et al*., 1997; Boukari *et al*., 2002) but they enhance the magnitude of spontaneous magnetization in the case of a p–i–n diode (Boukari *et al*., 2002). Furthermore, the current-induced magnetization reversal was demonstrated in submicron pillars of (Ga,Mn)As/GaAs/(Ga,Mn)As (Chiba *et al*., 2004; Elsen *et al*., 2006). Spin-polarized current was also shown to displace magnetic domain walls in (Ga,Mn)As with the easy axis perpendicular to the film plane (Yamanouchi, Chiba, Matsukura and Ohno, 2004, 2006).

Guided by the growing amount of experimental results, including informative magnetic resonance (Szczytko *et al*., 1999; Fedorych, Hankiewicz, Wilamowski and Sadowski, 2002) and photoemission (Mizokawa *et al*., 2002; Rader *et al*., 2004; Hwang *et al*., 2005) studies, a theoretical model of the hole-controlled ferromagnetism in III–V, II–VI, and group IV semiconductors containing Mn was proposed (Dietl *et al*., 2000, 2001). These materials exhibit characteristics specific to both charge transfer insulators and strongly correlated disordered metals. Moreover, complexities specific to strongly correlated systems coexist in DMS with features exhibited by heavily doped semiconductors and semiconductor alloys, such as Anderson–Mott localization (Dietl, 1994), defect generation by self-compensation mechanisms (Dietl, Ohno and Matsukura, 2001; Mašek and Máca, 2001; Yu *et al*., 2002), and the breakdown of the virtual-crystal approximation (Benoit à la Guillaume, Scalbert and Dietl, 1992). Nevertheless, the theory built on p–d Zener's model of carrier-mediated ferromagnetism and on either Kohn-Luttinger's kp (Dietl *et al*., 2000; Dietl, Ohno and Matsukura, 2001; Abolfath, Jungwirth, Brum and MacDonald, 2001) or multiorbital tight-binding (Vurgaftman and Meyer, 2001; Sankowski and Kacman, 2005; Timm and MacDonald, 2005) descriptions of the valence band in tetrahedrally coordinated semiconductors has qualitatively, and often quantitatively, described thermodynamic, micromagnetic, transport, and optical properties of DMS with delocalized holes (Dietl, 2004; Jungwirth *et al*., 2006a; Sankowski, Kacman, Majewski and Dietl, 2006a), challenging competing theories. It is often argued that owing to these studies (Ga,Mn)As has become one of the best-understood ferromagnets. Accordingly, this material is now serving as a testing ground for various *ab initio* computational approaches to strongly correlated and disordered systems.

2.2 Magnetic impurities in semiconductors

A good starting point for the description of DMS is the Vonsovskii model, according to which the electron states can be divided into two categories: (i) localized magnetic d or f shells and (ii) extended band states built up of s, p, and sometimes d atomic orbitals. The former give rise to the presence of local magnetic moments and intracenter optical transitions. The latter form bands, much alike as in the case of nonmagnetic semiconductor alloys. Indeed, the lattice constant of DMS obeys the Vegard low, and the energy gap E_g between the valence and the conduction band depends on x in a manner qualitatively similar to nonmagnetic counterparts. According to the Anderson model, the character of magnetic impurities in solids results from a competition between (i) hybridization of local and extended states, which tends to delocalized magnetic electrons and (ii) the on-site Coulomb interactions among the localized electrons, which stabilizes the magnetic moment in agreement with Hund's rule.

Figure 1 shows positions of local states derived from 3d shells of TM impurities with respect to the band energies

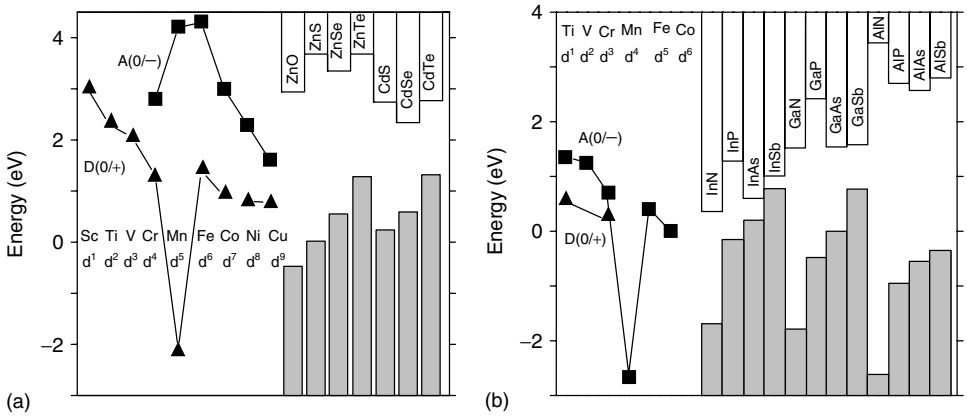

Figure 1. Approximate positions of transition-metal levels relative to the conduction and valence band edges of II–VI (a) and III–V (b) compounds. By triangles the d^N/d^{N-1} donor and by squares the d^N/d^{N+1} acceptor states are denoted. (Adapted from Langer, Delerue, Lannoo and Heinrich, 1988 and Zunger, 1986.)

of the host II–VI and III–V compounds. In Figure 1, the levels labeled 'donors' denote the ionization energy of the magnetic electrons ($TM^{2+} \rightarrow TM^{3+}$or $d^n \rightarrow d^{n-1}$), whereas the 'acceptors' correspond to their affinity energy ($TM^{2+} \rightarrow TM^{1+}$or $d^n \rightarrow d^{n+1}$). The difference between the two is the on-d-shell Coulomb (Hubbard) repulsion energy U in the semiconductor matrix. In addition, the potential introduced by either neutral or charged TM can bind a band carrier in a Zhang-Rice-type singlet or hydrogenic-like state, respectively. Such bound states are often experimentally important, particularly in III–V compounds, as they correspond to lower energies than the competing d-like states, such as presented in Figure 1.

In the case of Mn, in which the d shell is half-filled, the d-like donor state lies deep in the valence band, whereas the acceptor level resides high in the conduction band, so that $U \approx 7\,\text{eV}$ according to photoemission and inverse photoemission studies. Thus, Mn-based DMS can be classified as charge transfer insulators, $E_g < U$. The Mn ion remains in the 2+ charge state, which means that it does not supply any carriers in II–VI materials. However, it acts as a hydrogenic-like acceptor in the case of III–V antimonides and arsenides, while the corresponding Mn-related state is deep, presumably due to a stronger p–d hybridization, in the case of phosphides and nitrides. According to Hund's rule, the total spin $S = 5/2$ and the total orbital momentum $L = 0$ for the d^5 shell in the ground state. The lowest excited state d^{*5} corresponds to $S = 3/2$ and its optical excitation energy is about 2 eV. Thus, if there is no interaction between the spins, their magnetization is described by the paramagnetic Brillouin function. In the case of other TMs, the impurity-induced levels may appear in the gap, and then compensate shallow impurities, or even act as resonant dopant, for example, Sc in CdSe, Fe in HgSe or Cu in HgTe. Transport studies of such systems have demonstrated that intersite Coulomb interactions between charged ions lead to the Efros-Shklovskii gap in the density of the impurity states, which makes resonant scattering to be inefficient in semiconductors (Wilamowski, Świątek, Dietl and Kossut, 1990). Furthermore, spin-orbit interaction and Jahn–Teller effect control positions and splittings of the levels in the case of ions with $L \neq 0$. If the resulting ground state is a magnetically inactive singlet there is no permanent magnetic moment associated with the ion, the case of Fe^{2+}, whose magnetization is of the Van Vleck type at low temperatures.

2.3 Exchange interaction between band and localized spins

The important aspect of DMS is a strong spin-dependent coupling of the effective mass carriers to the localized d electrons, first discovered in (Cd,Mn)Te (Komarov *et al.*, 1977; Gaj, Gałązka and Nawrocki, 1978) and (Hg,Mn)Te (Bastard *et al.*, 1978; Jaczyński, Kossut and Gałązka, 1978). Neglecting nonscalar corrections that can appear for ions with $L \neq 0$, this interaction assumes the Kondo form,

$$H_K = -I(\vec{r} - \vec{R}^{(i)})\vec{s}\vec{S}^{(i)} \tag{1}$$

where $I(\vec{r} - \vec{R}^{(i)})$ is a short-range exchange energy operator between the carrier spin $\vec{s}$ and the TM spin localized at $\vec{R}^{(i)}$. When incorporated to the kp scheme, the effect of H_K is described by matrix elements $\langle u_i|I|u_i\rangle$, where u_i are the Kohn-Luttinger amplitudes of the corresponding band extreme. In the case of carriers at the Γ point of the Brillouin zone in zinc-blende DMS , the two relevant matrix elements $\alpha = \langle u_c|I|u_c\rangle$ and $\beta = \langle u_v|I|u_v\rangle$ involve s-type and p-types wave functions, respectively. There are two

mechanisms contributing to the Kondo coupling (Dietl, 1981; Bhattacharjee, Fishman and Coqblin, 1983; Kacman, 2001): (i) the exchange part of the Coulomb interaction between the effective mass and localized electrons; (ii) the spin-dependent hybridization between the band and local states. Since there is no hybridization between Γ_6 and d-derived (e_g and t_{2g}) states in zinc-blende structure, the s–d coupling is determined by the direct exchange. The experimentally determined values are of the order of $\alpha N_o \approx 0.25\,\mathrm{eV}$, where N_o is the cation concentration, somewhat reduced comparing to the value deduced from the energy difference between $S1/2$ states of the free singly ionized Mn atom $3d^5 4s^1$, $\alpha N_o = 0.39\,\mathrm{eV}$. In contrast, there is a strong hybridization between Γ_8 and t_{2g} states, which affects their relative position, and leads to a large magnitude of $|\beta N_o| \approx 1\,\mathrm{eV}$. If the relevant effective mass state is above the t_{2g} level (the case of, e.g., Mn-based DMS, $\beta < 0$ but otherwise β can be positive (the case of, e.g., $Zn_{1-x}Cr_xSe$ (Mac *et al.*, 1993)).

2.4 p–d Zener model

It is convenient to apply the Zener model of carrier-controlled ferromagnetism by introducing the functional of free-energy density, $\mathcal{F}[\vec{M}(\vec{r})]$. The choice of the local magnetization $\vec{M}(\vec{r})$ as an order parameter means that the spins are treated as classical vectors, and that spatial disorder inherent to magnetic alloys is neglected. In the case of magnetic semiconductors $\mathcal{F}[\vec{M}(\vec{r})]$ consists of two terms, $\mathcal{F}[\vec{M}(\vec{r})] = \mathcal{F}_S[\vec{M}(\vec{r})] + \mathcal{F}_c[\vec{M}(\vec{r})]$, which describe, for a given magnetization profile $\vec{M}(\vec{r})$, the free energy densities of the Mn spins in the absence of any carriers and of the carriers in the presence of the Mn spins, respectively. A visible asymmetry in the treatment of the carries and of the spins corresponds to an adiabatic approximation: the dynamics of the spins in the absence of the carriers is assumed to be much slower than that of the carriers. Furthermore, in the spirit of the virtual-crystal and molecular-field approximations, the classical continuous field $\vec{M}(\vec{r})$ controls the effect of the spins upon the carriers. Now, the thermodynamics of the system is described by the partition function Z, which can be obtained by a functional integration of the Boltzmann factor $\exp(-\int \mathrm{d}\vec{r}\mathcal{F}[\vec{M}(\vec{r})]/k_B T)$ over all magnetization profiles $\vec{M}(\vec{r})$, an approach developed for bound magnetic polarons (Dietl and Spałek, 1983; Dietl, 1983), and directly applicable for spin physics in quantum dots as well. In the mean-field approximation (MFA), which should be valid for spatially extended systems and long-range spin–spin interactions, a term corresponding to the minimum of $\mathcal{F}[\vec{M}(\vec{r})]$ is assumed to determine Z with a sufficient accuracy.

If energetics is dominated by spatially uniform magnetization $\vec{M}$, the spin part of the free energy density in the magnetic field $\vec{H}$ can be written in the form (Świerkowski and Dietl, 1988)

$$\mathcal{F}_S[\vec{M}] = \int_0^{\vec{M}} \mathrm{d}\vec{M}_o \vec{h}(\vec{M}_o) - \vec{M}\vec{H} \tag{2}$$

Here, $\vec{h}(\vec{M}_o)$ denotes the inverse function to $\vec{M}_o(\vec{h})$, where $\vec{M}_o$ is the available experimentally macroscopic magnetization of the spins in the absence of carriers in the field h and temperature T. In DMS, it is usually possible to parameterize $M_o(h)$ by the Brillouin function $B_S(T, H)$ that takes the presence of intrinsic short-range antiferromagnetic interactions into account. Near T_C and for $H = 0$, M is sufficiently small to take $M_o(T, h) = \chi(T)h$, where $\chi(T)$ is the magnetic susceptibility of localized spins in the absence of carriers. Under these conditions,

$$\mathcal{F}_S[M] = \frac{M^2}{2\chi(T)} \tag{3}$$

which shows that the increase of $\mathcal{F}_S$ with M slows down with lowering temperature, where $\chi(T)$ grows. Turning to $\mathcal{F}_c[M]$ we note that owing to the giant Zeeman splitting of the bands proportional to M, the energy of the carriers, and thus $\mathcal{F}_c[M]$, decreases with $|M|$, $\mathcal{F}_c[M] - \mathcal{F}_c[0] \sim -M^2$. Accordingly, a minimum of $\mathcal{F}[M]$ at nonzero M may develop in $H = 0$ at sufficiently low temperatures signalizing the appearance of a ferromagnetic order.

The present authors and coworkers (Dietl *et al.*, 2000) found that the minimal Hamiltonian necessary to describe properly effects of the complex structure of the valence band in tetrahedrally coordinated semiconductors upon $\mathcal{F}_c[M]$ is the Luttinger $6 \times 6\,kp$ model supplemented by the p–d exchange contribution taken in the virtual-crystal and molecular-field approximations,

$$H_{pd} = \frac{\beta \vec{s}\vec{M}}{g\mu_B} \tag{4}$$

This term leads to spin splittings of the valence subbands, whose magnitudes – owing to the spin-orbit coupling – depend on the hole wave vectors $\vec{k}$ in a complex way even for spatially uniform magnetization $\vec{M}$. It would be technically difficult to incorporate such effects to the Ruderman-Kittel-Kasuya-Yosida (RKKY) model, as the spin-orbit coupling leads to nonscalar terms in the spin–spin Hamiltonian. At the same time, the indirect exchange associated with the virtual spin excitations between the valence subbands, the Bloembergen-Rowland mechanism, is automatically included. The model allows for strain, confinement, and was developed for both zinc-blende and wurzite materials (Dietl, Ohno and Matsukura, 2001). Furthermore, the direct influence of the magnetic field on the hole spectrum

was taken into account. Carrier–carrier spin correlation was described by introducing a Fermi-liquid-like parameter A_F (Dietl, Haury and Merle d'Aubigné, 1997; Haury *et al*., 1997; Jungwirth, Atkinson, Lee and MacDonald, 1999), which enlarges the Pauli susceptibility of the hole liquid. No disorder effects were taken into account on the ground that their influence on thermodynamic properties is relatively weak except for strongly localized regime. Having the hole energies, the free energy density $\mathcal{F}_c[\vec{M}]$ was evaluated according to the procedure suitable for Fermi liquids of arbitrary degeneracy. By minimizing $\mathcal{F}[\vec{M}] = \mathcal{F}_S[\vec{M}] + \mathcal{F}_c[\vec{M}]$ with respect to $\vec{M}$ at given T, H, and hole concentration p, Mn spin magnetization $M(T, H)$ was obtained as a solution of the mean-field equation,

$$\vec{M}(T, H) = x_{\text{eff}} N_o g \mu_B S B_S \left[\frac{g\mu_B \left(-\frac{\partial \mathcal{F}_c[\vec{M}]}{\partial \vec{M}} + \vec{H} \right)}{k_B (T + T_{AF})} \right] \quad (5)$$

where the carrier energy and entropy as well as peculiarities of the valence band structure, such as the presence of various hole subbands, anisotropy, and spin-orbit coupling, are hidden in $F_c[\vec{M}]$. Near the Curie temperature T_C and at $H = 0$, where M is small, we expect $\mathcal{F}_c[M] - \mathcal{F}_c[0] \sim -M^2$. It is convenient to parameterize this dependence by a generalized carrier spin susceptibility, which is related to the magnetic susceptibility of the carrier liquid according to $\chi_c = A_F (g^* \mu_B)^2 \tilde{\chi}_c$. In terms of $\tilde{\chi}_c$,

$$\mathcal{F}_c[M] = \mathcal{F}_c[0] - \frac{A_F \tilde{\chi}_c \beta^2 M^2}{2(g\mu_B)^2} \quad (6)$$

By expanding $B_S(M)$ for small M one arrives to the mean-field formula for $T_C = T_F - T_{AF}$, where T_F is given by

$$T_F = \frac{x_{\text{eff}} N_o S(S+1) A_F \tilde{\chi}_c(T_C) \beta^2}{3k_B} \quad (7)$$

For a strongly degenerate carrier liquid $|\epsilon_F|/k_B T \gg 1$, as well as neglecting the spin-orbit interaction $\tilde{\chi}_c = \rho/4$, where ρ is the total density of states for intraband charge excitations, which in the 3D case is given by $\rho = m^*_{DOS} k_F / \pi^2 \hbar^2$. In this case and for $A_F = 1$, T_F assumes the well-known form, derived already in 1940s in the context of carrier-mediated nuclear ferromagnetism (Fröhlich and Nabarro, 1940). In general, however, $\tilde{\chi}_c$ has to be determined numerically by computing $\mathcal{F}_c[M]$ for a given band structure and degeneracy of the carrier liquid. The model can readily be generalized to various dimensions as well as to the case, when $\vec{M}$ is not spatially uniform in the ground state, a case of spin-density waves expected in the case of 1D systems.

The same formalism, in addition to T_C and Mn magnetization $M(T, H)$, as discussed in the preceding text, provides also quantitative information on spin polarization and magnetization of the hole liquid (Dietl, Ohno and Matsukura, 2001). Furthermore, it can be exploited to describe chemical trends as well as micromagnetic, transport, and optical properties of ferromagnetic DMS (Jungwirth *et al*., 2006a). In particular, a detail theoretical analysis of anisotropy energies and anisotropy fields in films of (Ga,Mn)As was carried out for a number of experimentally important cases within the p–d Zener model (Dietl, Ohno and Matsukura, 2001; Abolfath, Jungwirth, Brum and MacDonald, 2001). The cubic anisotropy as well as uniaxial anisotropy under biaxial epitaxial strain were examined as a function of the hole concentration p. Both shape and magnetocrystalline anisotropies were taken into account. The perpendicular and in-plane orientation of the easy axis is expected for the compressive and tensile strain, respectively, provided that the hole concentration is sufficiently small. However, according to theory, a reorientation of the easy axis direction is expected at higher hole concentrations. Furthermore, in a certain concentration range the character of magnetic anisotropy is found to depend on the magnitude of spontaneous magnetization, that is on the temperature. The computed phase diagram for the reorientation transition compared to the experimental results for a (Ga,Mn)As film is shown in Figure 2. In view that theory is developed with no adjustable parameters the agreement between experimental and computed concentrations and temperature corresponding to the reorientation transition is very good. Furthermore, the computed magnitudes of the anisotropy field H_u (Dietl, Ohno and Matsukura, 2001) are consistent with the available findings for both compressive and tensile strain.

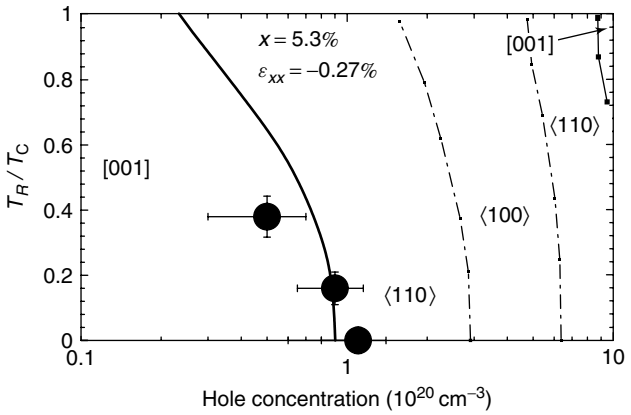

Figure 2. Experimental (full points) and computed values (thick lines) of the ratio of the reorientation to Curie temperature for the transition from perpendicular to in-plane magnetic anisotropy. Dashed lines mark expected temperatures for the reorientation of the easy axis between ⟨100⟩ and ⟨110⟩ in-plane directions. (Reproduced from Sawicki *et al*., 2005, with permission from the American Physical Society. © 2005.)

It should be emphasized that the preceding description of ferromagnetic DMS is strictly valid only in the weak coupling limit (Dietl *et al*., 2000). On going from antimonides to nitrides or from tellurides to oxides, the p–d hybridization increases. In the strong-coupling limit, the short-range part of the TM potential may render the virtual-crystal approximation and molecular-field approximation invalid (Benoit à la Guillaume, Scalbert and Dietl, 1992; Matsukura and Ohno, 2002), leading to properties somewhat reminiscent of those specific to alloys which cannot be described by the virtual crystal approximation, like Ga(As,N) (Wu, Shan and Walukiewicz, 2002). Here, dynamic mean-field approximation (DMFA) may capture relevant physics (Chattopadhyay, Das Sarma and Millis, 2001). In particular, in the strong-coupling limit, the short-range potential of the TM ion admixes to the itinerant carrier wave function a local component. This, together with quantum effects of Anderson–Mott localization, may generate modifications in optical and transport characteristics, such as an apparent increase in the carrier effective mass (Burch *et al*., 2006).

The issue how various corrections to the mean-field p–d Zener model (Dietl *et al*., 2000) affect theoretical values of T_C was recently examined in some detail for (Ga,Mn)As (Brey and Gómez-Santos, 2003; Timm and MacDonald, 2005; Jungwirth *et al*., 2005; Popescu *et al*., 2006) with the conclusions that the overall picture remains quantitatively valid. Figure 3 shows one of the recent theoretical modelings of T_C in comparison to experimental findings for (Ga,Mn)As (Jungwirth *et al*., 2005). These results confirm, in particular, that T_C values above 300 K could be achieved in $Ga_{0.9}Mn_{0.1}As$ if such a large magnitude of the substitutional Mn concentration could be accompanied by a corresponding increase of the hole density (Dietl *et al*., 2000).

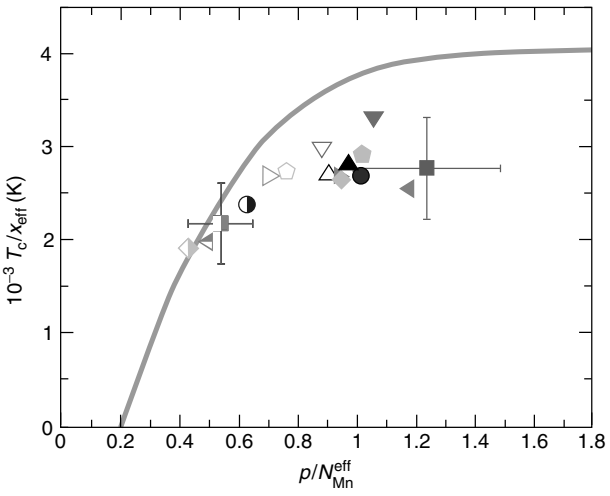

Figure 3. Experimental Curie temperatures versus hole density p relative to effective concentration of Mn moments, $N_{Mn} = 4x_{eff}/a_o^3$, where x_{eff} is the content of Mn in the substitutional positions and a_o is the lattice constant. Gray line is theoretical computed within the tight-binding and coherent potential approximations. 2.5 Theory of modulated structures of diluted ferromagnetic semiconductors

The discovery of carrier-induced ferromagnetism in zinc-blende III–V and II–VI compounds has made it possible to consider physical phenomena and device concepts for previously unavailable combinations of quantum structures and magnetism in semiconductors. Indeed, it has already been demonstrated that various modulated structures of (Ga,Mn)As show functionalities relevant for spintronic devices including spin injection of holes (Ohno *et al*., 1999; Young *et al*., 2002) and electrons (Kohda *et al*., 2001, 2006; Johnston-Halperin *et al*., 2002), interlayer coupling (Chiba *et al*., 2000; Sadowski *et al*., 2002), exchange bias (Eid *et al*., 2005), giant magnetoresistance (GMR) (Chiba *et al*., 2000), tunneling magnetoresistance (TMR) (Tanaka and Higo, 2001; Mattana *et al*., 2003; Chiba, Matsukura and Ohno, 2004), tunneling anisotropic magnetoresistance (TAMR) (Ruster *et al*., 2005; Giddings *et al*., 2005), and domain-wall resistance (Tang *et al*., 2004; Chiba *et al*., 2006).

Because of paramount importance of interfaces as well of Rashba and Dresselhaus terms, spin properties of modulated semiconductor structures cannot be meaningfully modeled employing a standard kp theory. Accordingly, an empirical multiorbital tight-binding theory of multilayer structures has been developed (Oszwałdowski, Majewski and Dietl, 2006; Sankowski and Kacman, 2005; Sankowski, Kacman, Majewski and Dietl, 2006a,b). The employed procedure describes properly the carrier dispersion in the entire Brillouin zone and takes into account the presence of magnetic ions in the virtual-crystal and molecular-field approximations. Furthermore, since the phase coherence and spin diffusion lengths are comparable in these devices and, moreover, they are typically longer than the length of the active region, the formulation of spin transport model in terms of the Boltzmann distribution function f for particular spin orientations is not appropriate. Recently, theory that combines a Landauer-Büttiker formalism with tight-binding approximation has been developed (van Dorpe *et al*., 2005; Sankowski, Kacman, Majewski and Dietl, 2006a,b). In contrast to the standard kp method (Petukhov, Chantis and Demchenko, 2002; Brey, Fernández-Rossier and Tejedor, 2004), this theory, in which $sp^3d^5s^*$ orbitals are taken into account, describes properly the interfaces and inversion symmetry breaking as well as the band dispersion in the entire Brillouin zone, so that the essential for the spin-dependent tunneling Rashba and

Dresselhaus terms as well as the tunneling via $\vec{k}$ points away from the zone center are taken into account.

The approach in question, developed with no adjustable parameters, provided information on sign of the interlayer coupling (Sankowski and Kacman, 2005), explained experimentally observed large magnitudes of both electron current spin polarization up to 70% in the (Ga,Mn)As/n-GaAs Zener diode (van Dorpe *et al*., 2005) and TMR of the order of 300% in a (Ga,Mn)As/GaAs/(Ga,Mn)As trilayer structure (Sankowski, Kacman, Majewski and Dietl, 2006b), as shown in Figure 4. Furthermore, theory reproduced a fast decrease of these figures with the device bias as well as it indicated that the magnitude of TAMR should not exceed 10% under usual strain conditions and for hole densities corresponding to the metal side of the metal-to-insulator transition (MIT) (Sankowski, Kacman, Majewski and Dietl, 2006a). A similar model was employed to examine an intrinsic domain-wall resistance in (Ga,Mn)As (Oszwałdowski, Majewski and Dietl, 2006).

3 NONUNIFORM FERROMAGNETIC DMS – ELECTRONIC NANOSCALE PHASE SEPARATIONS

3.1 Effects of competing magnetic interactions

A number of effects has been identified, which may lead to deviations from a simple ferromagnetic spin order in carrier-controlled diluted ferromagnetic semiconductors even if the spatial distribution of magnetic ions is uniform. In particular, spin-density waves appear to be in the ground state in the case of 1D systems (Dietl, Cibert, Ferrand and Merle d'Aubigné, 1999). Another proposal involves canted ferromagnetism stemming from a nonscalar form of spin–spin interactions, brought about by spin-orbit coupling (Zaránd and Jankó, 2002), though a large value of saturation magnetization in (Ga,Mn)As indicates that the effect is not large (Jungwirth *et al*., 2006b). Finally, a competition between long-range ferromagnetic interactions and intrinsic short-range antiferromagnetic interactions (Kępa *et al*., 2003) may affect the character of magnetic order (Kechrakos, Papanikolaou, Trohidou and Dietl, 2005). It appears that the effect is more relevant in II–VI DMS than in III–V DMS where Mn centers are ionized, so that the enhanced hole density at closely lying Mn pairs may compensate antiferromagnetic interactions (Dietl, Ohno and Matsukura, 2001).

The above-mentioned competition between the long-range RKKY merely ferromagnetic interaction and short-range merely antiferromagnetic superexchange was shown to affect in a nontrivial way magnetic properties of modulation-doped p-type (Cd,Mn)Te quantum wells (Kechrakos, Papanikolaou, Trohidou and Dietl, 2005). In this system, the temperature T_C at which spontaneous spin splitting of electronic levels appears as well as its temperature dependence (Haury *et al*., 1997; Kossacki *et al*., 2000, 2002; Boukari *et al*., 2002) follow predictions of a simple mean-field Zener-like model of ferromagnetism (Dietl, Haury and Merle d'Aubigné, 1997). A reasonable accuracy of the MFA in this low-dimensional system was linked to the long-range

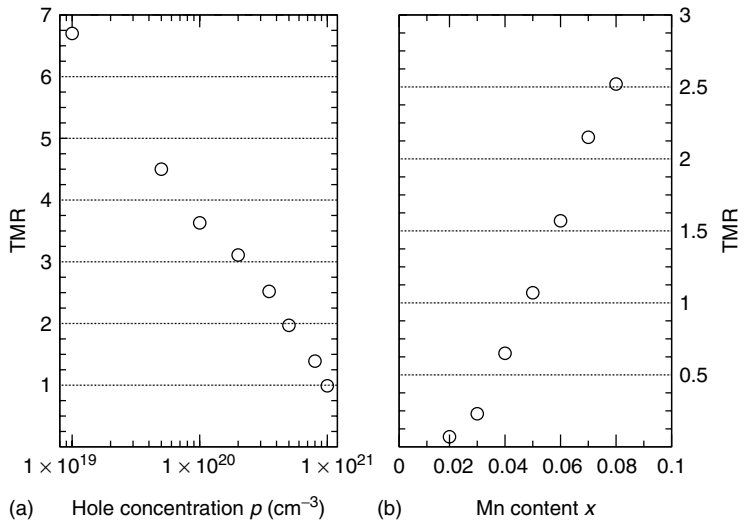

Figure 4. Difference in resistance for antiparallel and parallel magnetization orientations normalized by resistance for parallel orientation for tunneling structures p-$Ga_{1-x}Mn_xAs$/GaAs/p-$Ga_{1-x}Mn_xAs$ as a function of: (a) hole concentration p (for $x = 0.08$); (b) Mn content x (for $p = 3.5 \times 10^{20}\,\mathrm{cm}^{-3}$) in the limit of small bias voltage. (Reproduced from Sankowski, P. *et al*., 2006, with permission from Elsevier. © 2006.)

character of the ferromagnetic interactions as well as to the combined effects of spin-orbit interaction and confinement that lead to the Ising-type universality class (Haury *et al*., 1997). At the same time, however, wide hysteresis loops and the associated spontaneous macroscopic magnetization in zero magnetic field, which are expected within this model (Lee, Jungwirth and MacDonald, 2002), have not been observed. Instead, according to polarization-resolved photoluminescence measurements, the global spin polarization of the carrier liquid increases slowly with the external magnetic field along the easy axis, reaching saturation at a field by a factor of 20 greater than what could be accounted for by demagnetization effects (Kossacki *et al*., 2000, 2002).

In order to explain this behavior, Monte Carlo simulations were employed (Kechrakos, Papanikolaou, Trohidou and Dietl, 2005), in which the Schrödinger equation was solved at each Monte Carlo sweep. Such a model is capable to assess the influence of magnetization fluctuations, short-range antiferromagnetic interactions, disorder, magnetic polaron formation, and spin-Peierls instability on the carrier-mediated ferromagnetism in two-dimensional electronic systems. It has been found that the determined critical temperatures and hystereses are affected in a nontrivial way by the presence of short-range antiferromagnetic interactions, as shown in Figure 5. In particular, the antiferromagnetic interactions decrease T_C less than expected within the MFA. However, the presence of competing interactions reduces strongly the remanence and the coercive field. It appears that in order to satisfy both ferromagnetic and antiferromagnetic spin couplings in an optimum way, the system breaks into nanoscale ferromagnetic domains, so that the global magnetization averages to zero. At the same time, the magnitude of the external magnetic field that can align these domains is set by the strength of the antiferromagnetic interactions, not by demagnetization or magnetic anisotropy energies.

3.2 Effects of Anderson–Mott localization

Similar to other doped semiconductors, p-type DMS undergo MIT, when an average distance between the carriers becomes 2.5 times greater than the Bohr radius. The insulator regime can be reached not only by reducing the acceptor density but also by increasing the concentration of compensation donors or by depleting the film of holes either by electrostatic gates or by charge transfer to surface states or to neighbor undoped layers. In has been found that, in contrast to charge transport characteristics, the Curie temperature, like other thermodynamic properties, does not show up any critical behavior on crossing the MIT (Matsukura, Ohno, Shen and Sugawara, 1998; Ferrand *et al*., 2001).

Two competing models have been put forward in order to explain the existence of ferromagnetic order on the insulator side of the MIT. According to the magnetic polaron scenario (Durst, Bhatt and Wolff, 2002; Kaminski and Das Sarma, 2002) the holes stay localized by the individual parent acceptors, so that their localization length corresponds to the Bohr radius, usually diminished – particularly in the strong-coupling regime – by the hole interaction with the short-range part of the TM potential. In such a case, the ferromagnetic transition can be viewed as the percolation threshold of bound magnetic polarons.

Another scenario was put forward by the present author and coworkers (Dietl, Haury and Merle d'Aubigné, 1997; Dietl *et al*., 2000; Ferrand *et al*., 2001). Within this model, the hole localization length, which diverges at the MIT,

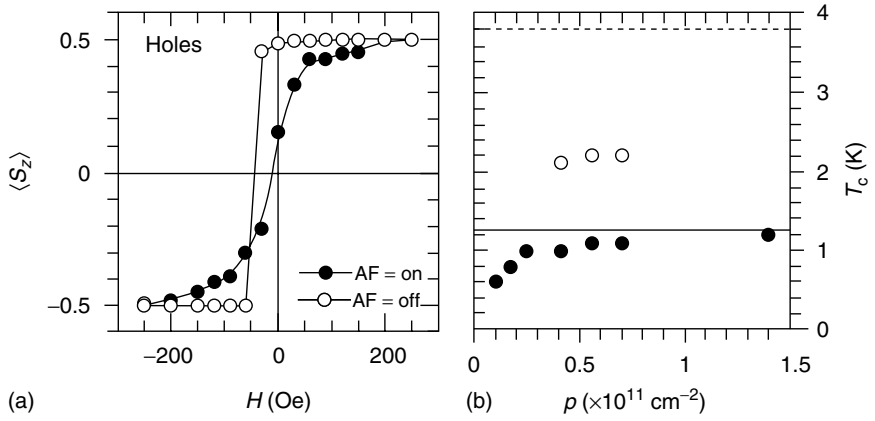

Figure 5. (a) Upper branch of the magnetization hysteresis loop of hole spins in a $Cd_{0.96}Mn_{0.04}Te$ quantum well at $T = 0.7T_C$, where T_C is the Curie temperature, as determined by Monte Carlo simulations neglecting (open symbols) an taking into account (full symbols) the presence of antiferromagnetic interactions. The sheet hole density is $p = 0.41 \times 10^{11}\,cm^{-2}$. (b) The simulated dependence of T_C on p. Horizontal lines are the mean-field results neglecting (dashed line) and taking into account (solid line) antiferromagnetic interactions. (Reproduced from Kechrakos *et al*., 2005, with permission from the American Physical Society. © 2005.)

remains much greater than an average distance between the acceptors for the experimentally important range of the hole densities. Accordingly, the holes can be regarded as delocalized at the length scale relevant for the coupling between magnetic ions. Hence, the spin–spin exchange interactions are effectively mediated by the itinerant carriers, so that the p–d Zener or RKKY model can be applied also on the insulator side of the MIT. At the same time, however, large mesoscopic fluctuations in the local value of the density of states are expected near the MIT. As a result, nanoscale phase separation into paramagnetic and ferromagnetic regions takes place below and in the vicinity of the apparent Curie temperature. The paramagnetic phase persists down to the lowest temperatures in the locations that are *not* visited by the holes or characterized by a low value of the blocking temperature T_B defined in Introduction. The ferromagnetic order develops in the regions, where the carrier liquid sets long-range ferromagnetic correlation between the randomly distributed TM spins. According to this model, the portion of the material encompassing the ferromagnetic bubbles, and thus the magnitude of the saturated ferromagnetic moment, grows with the net acceptor concentration, extending over the whole sample on the metallic side of the MIT.

It is still a formidable task, even in nonmagnetic semiconductors, to describe quantitatively effects of both disorder and carrier–carrier correlation near the Anderson–Mott transition. However, there is a growing amount of experimental results indicating that the model outlined in the previous paragraph is qualitatively correct. In particular, for samples on the insulator side of MIT, the field dependence of magnetization shows the presence of superimposed ferromagnetic and paramagnetic contributions in both (Ga,Mn)As (Oiwa *et al*., 1997) and p-(Zn,Mn)Te (Ferrand *et al*., 2001). Interestingly, the paramagnetic component is less visible in the anomalous Hall effect data, presumably because it probes merely the regions visited by the carriers (Ferrand *et al*., 2001). At the same time, colossal negative magnetoresistance is observed, leading to the field-induced insulator-to-metal transition in samples with the appropriate acceptor densities (Ferrand *et al*., 2001; Katsumoto *et al*., 1998). The enhanced conductance in the magnetic field can be linked to the ordering of ferromagnetic bubbles and to the alignment of the spins in the paramagnetic regions. Remarkably, the corresponding effects have recently been found in modulation-doped quantum well of (Cd,Mn)Te, where no localization of carriers by individual ionized impurities and, thus, no formation of bound magnetic polarons is expected (Jaroszyński *et al*., 2005). The question whether the holes bound by individual acceptors or rather the holes residing in weakly localized states mediate ferromagnetism in DMS on the insulating side of the MIT was also addressed by inelastic neutron scattering in (Zn,Mn)Te:P (Kępa *et al*., 2003). In that work, the difference in the nearest-neighbor Mn pairs exchange energy J_1 in the presence and in the absence of the holes was determined. The hole-induced contribution to J_1 was found to be by a factor of 4 smaller than that calculated under the assumption that the holes reside on individual acceptors. By contrast, if the hole states are assumed to be metallic-like at length scale of the nearest-neighbor distance, the calculated value is smaller than the experimental one by a factor of 1.5, a discrepancy well within combine uncertainties in the input parameters to theory and experimental determination.

4 NONUNIFORM FERROMAGNETIC DMS – CHEMICAL NANOSCALE PHASE SEPARATIONS

4.1 Spinodal decomposition

It is well known that phase diagrams of a number of alloys exhibit a solubility gap in a certain concentration range. This may lead to spinodal decomposition into regions with a low and a high concentration of particular constituents. If the concentration of one of them is small, it may appear in a form of coherent nanocrystals embedded by the majority component. For instance, such a spinodal decomposition is known to occur in the case of (Ga,In)N (Farhat and Bechstedt, 2002), where In-rich quantum-dot-like regions are embedded by an In-poor matrix. However, according to the pioneering *ab initio* work of van Schilfgaarde and Mryasov (2001) and others (Sato, Katayama-Yoshida and Dederichs, 2005) particularly strong tendency to form nonrandom alloy occurs in the case of DMS: the evaluated gain in energy by bringing two Ga-substitutional Mn atoms together is $E_d = 120\,\text{meV}$ in GaAs and 300 meV in GaN, and reaches 350 meV in the case of Cr pair in GaN (van Schilfgaarde and Mryasov, 2001).

Since spinodal decomposition does not usually involve a precipitation of another crystallographic phase, it is not easy detectable experimentally. Nevertheless, its presence was found by transmission electron microscopy (TEM) (Moreno *et al*., 2002; Yokoyama, Yamaguchi, Ogawa and Tanaka, 2005) in (Ga,Mn)As, where coherent zinc-blende Mn-rich (Mn,Ga)As nanocrystals led to the apparent Curie temperature up to 360 K (Yokoyama, Yamaguchi, Ogawa and Tanaka, 2005). Furthermore, coherent hexagonal and diamond-type Mn-rich nanocrystals were detected by spatially resolved X-ray diffraction in (Ga,Mn)N (Martinez-Criado *et al*., 2005) and by TEM in (Ge,Mn) (Bougeard, Ahlers, Trampert and Abstreiter, 2006), respectively.

In view of typically limit solubility of magnetic atoms in semiconductors, it may, therefore, be expected that such a

spinodal decomposition is a generic property of a number of DMS. Owing to the high concentration of the magnetic constituent, the nanocrystals form in this way order magnetically at a relatively high temperature T_m, usually much greater than room temperature. Obviously, either ferromagnetic or ferrimagnetic nanocrystals possess a nonzero magnetic moment. Interestingly enough, nanocrystals in which antiferromagnetic interactions dominate can also show a nonzero magnetic moment owing to the presence of uncompensated spins at their surface, whose relative magnitude grows with decreasing nanocrystal size (Trohidou, Zianni and Blackman, 2002).

As an example we consider (Zn,Cr)Se (Karczewski *et al*., 2003) and (Zn,Cr)Te (Saito, Zayets, Yamagata and Ando, 2003), which show (Karczewski *et al*., 2003; Kuroda *et al*., 2005) the well-known superparamagnetic behavior (Shinde *et al*., 2004; Goswami *et al*., 2005), indicating that the system is to be viewed rather as an ensemble of noninteracting ferromagnetic particles than a uniform magnetic alloy. In such a case the temperature dependencies of magnetization and magnetic susceptibility are described by four distinguished temperatures: T_m, the blocking temperature T_B that corresponds to a maximum of zero-field cooled magnetization; the apparent Curie temperature $T_C^{(app)}$ of the composite material, and the Curie–Weiss temperature Θ characterizing a weighted magnitude of the exchange interactions between the Cr spins within the nanocrystal. A maximum value of $T_C^{(app)} \approx 320\,\mathrm{K}$ is obtained for (Zn,Cr)Te with x_{Cr} above the percolation limit for 3D, $x \approx 0.2$.

These remarkable observations can readily be interpreted under the assumption that the relevant magnetic nanoparticles are built of a metallic zinc-blende CrTe or Cr-rich (Zn,Cr)Te characterized by $T_m \approx 320\,\mathrm{K}$ and by the lattice constant imposed by a paramagnetic semiconductor host, either ZnTe or (Zn,Cr)Te with a rather small Cr concentration. This conjecture is consistent with *ab initio* computations (Zhao and Zunger, 2005) predicting zinc-blende CrTe to be a ferromagnetic half-metal as well as with experimental results for CrTe in a bulk NiAs-type structure for which $T_m \equiv T_C = 340 \pm 10\,\mathrm{K}$ (Ohta, Kanomata, Kaneko and Yoshida, 1993). Within this scenario, for small ferromagnetic nanocrystals we expect $T_B < T_C^{(app)} < T_C$, T_B being proportional to a mean nanoparticle volume V, $T_B \approx KV/(25k_B)$, where K is the density of the magnetic anisotropy energy. Similarly, $T_C^{(app)}$ provides information on the upper bound of the V distribution. Furthermore, we note that broken magnetic bonds at the nanocrystal surface reduce the Curie–Weiss temperature Θ from its anticipated value for large V, $\Theta_{max} \geq T_C$.

It is, therefore, legitimate to suppose that coherent nanocrystals with a large concentration of magnetic constituent account for high apparent Curie temperatures detected in a number of DMS. This model explains, in particular, a long staying puzzle about the origin of ferromagnetic response in DMS, in which an average concentration of magnetic ions is below the percolation limit for the nearest neighbor coupling and, at the same time, the free-carrier density is too low to mediate an efficient long-range exchange interaction. Remarkably, the presence of magnetically active nanocrystals leads to an enhanced magneto-optical (Yokoyama, Yamaguchi, Ogawa and Tanaka, 2005) and magnetotransport (Shinde *et al*., 2004; Ye *et al*., 2003) properties. This opens doors for various applications of such hybrid systems provided that methods for controlling nanocrystal characteristics and distribution would be elaborated. So far, the most rewarding method of self-organized growth of coherent nanocrystals or quantum dots has exploited strain fields generated by lattice mismatch at interfaces of heterostructures (Stangl, Holý and Bauer, 2004). Remarkably, it becomes possible to fabricate highly ordered three-dimensional dot crystals under suitable spatial strain anisotropy (Stangl, Holý and Bauer, 2004). A further progress in this direction is particularly timely as it could result in the development of high-density 3D memories and spatial light modulators for advanced display technologies. A new method of self-organized growth has recently been proposed by the present author (Dietl, 2006). In this approach, long-range Coulomb forces serve to control the aggregation of alloy constituents.

4.2 Controlling spinodal decomposition by interion coulomb interactions

It is well known that in most DMS the levels derived from the open d or f shells of magnetic ions reside in the band gap of the host semiconductor (Dietl, 2002). This property of magnetic ions has actually been exploited for a long time to fabricate semi-insulating materials, in which carriers introduced by residual impurities or defects are trapped by the band-gap levels of magnetic impurities. The essential ingredient of the proposal in question (Dietl, 2006) is the observation that such a trapping alters the charge state of the magnetic ions and, hence, affect their mutual Coulomb interactions. Accordingly, codoping of DMS with shallow acceptors or donors modifies E_d and thus provides a mean for the control of ion aggregation. Indeed, the energy of the Coulomb interaction between two elementary charges residing on the nearest-neighbor cation sites in the GaAs lattice is 280 meV. This value indicates that the Coulomb interaction can preclude the aggregation, as the gain of energy associated with the bringing two Mn atoms in (Ga,Mn)As is $E_d = 120\,\mathrm{meV}$.

It is evident that the model in question should apply to a broad class of DMS as well to semiconductors and insulators, in which a constituent, dopant, or defect can exist

in different charge states under various growth conditions. As important examples we consider (Ga,Mn)N and (Zn,Cr)Te, in which remarkable changes in ferromagnetic characteristics on codoping with shallow impurities have recently been reported (Reed *et al*., 2005; Ozaki *et al*., 2005). In particular, a strong dependence of saturation magnetization M_s at 300 K on codoping with Si donors and Mg acceptors has been found (Reed *et al*., 2005) for (Ga,Mn)N with an average Mn concentration $x_{Mn} \approx 0.2\%$. Both double exchange and superexchange are inefficient at this low Mn concentration and for the midgap Mn level in question. At the same time, the model of nanocrystal self-organized growth in question explains readily why M_s goes through a maximum when Mn impurities are in the neutral Mn^{3+} state, and vanishes if codoping by the shallow impurities makes all Mn atoms to be electrically charged.

It has also been found that $T_C^{(app)}$ depends dramatically on the concentration of shallow N acceptors in (Zn,Cr)Te. Actually, $T_C^{(app)}$ decreases monotonically when the concentration x_N of nitrogen increases, and vanishes when x_{Cr} and x_N become comparable. This supports the model as in ZnTe the Cr state (Godlewski and Kamińska, 1980) resides about 1 eV above the nitrogen level (Baron, Saminadayar and Magnea, 1998). Accordingly, for $x_N \approx x_{Cr}$ all Cr atoms become ionized and the Coulomb repulsion precludes the nanocrystal formation. At the same time, the findings are not consistent with the originally proposed double exchange mechanism (Ozaki *et al*., 2005), as undoped ZnTe is only weakly p type, so that T_C should be small for either $x_N \approx 0$ and $x_N \approx x_{Cr}$, and pick at $x_N \approx x_{Cr}/2$, not at $x_N \approx 0$.

Finally, we mention the case of Mn doped GaAs, InAs, GaSb, and InSb. In those materials, owing to a relatively shallow character of Mn acceptors and a large Bohr radius, the holes reside in the valence band. Thus, the Mn atoms are negatively charged, which – according to our model – reduces their clustering, and makes it possible to deposit, by low-temperature epitaxy, a uniform alloy with a composition beyond the solubility limit. Codoping with shallow donors, by reducing the free-carrier screening, will enhance repulsions among Mn, and allow one to fabricate homogenous layers with even greater x_{Mn}. On the other hand, codoping by shallow acceptors, along with the donor formation by a self-compensation mechanism (Yu *et al*., 2002), will enforce the screening and, hence, lead to nanocrystal aggregation.

5 SUMMARY

The findings discussed here demonstrate that a number of pertinent properties of spatially uniformed carrier-controlled diluted ferromagnetic semiconductors and their heterostructures can be understood qualitatively, if not quantitatively, by the present theory. The accumulated data point clearly to the importance of spin-orbit interactions in the physics of hole-mediated ferromagnetism in semiconductors. These interactions control the magnitude of the Curie temperature, the saturation value of the magnetization, the anomalous Hall effect as well as the character and magnitude of magnetic and transport anisotropies. A growing amount of evidences shows that under various conditions the spatial distribution of carriers and/or magnetic ions is by no means uniform. The nanoscale phase separation can be driven either by randomness in the carrier and spin subsystems or by limited solubility of TMs in the host semiconductor, which leads to spinodal decomposition into regions with a small and a large concentration of the magnetic constituent. Interestingly, by manipulating the charge state of magnetic ions, it becomes possible to control the spinodal decomposition. This constitutes an appealing avenue toward self-organized coherent epitaxy of magnetic nanocrystals over a wide range of their dimensions. It is expected that further works will indicate how to tailor nanocrystal size dispersion and spatial distribution. In this context, engineering of local strains by exploiting various combinations of dopants and hosts may turn out to be of relevance. The self-organized growth mode in question (Dietl, 2006) is rather universal – it applies to dopants exhibiting a solubility gap, and different charge states that are stable under the growth conditions. The existence of this nano-assembling mechanism, as exemplified here by the case of (Zn,Cr)Te and (Ga,Mn)N codoped with shallow impurities, explains outstanding properties of a broad class of composite DMS, and offer prospects for exploiting their novel functionalities. In particular, the nanocrystals, rather than the host, are shown to account for ferromagnetic signatures in magnetic and magneto-optical characteristics of these systems. These findings imply also that today's *ab initio* methods of computational materials science, assigning the high-temperature ferromagnetism of, for example, (Zn,Cr)Te (Bergqvist *et al*., 2004; Fukushima, Sato, Katayama-Yoshida and Dederichs, 2004) to the uniform diluted alloy, overestimate substantially long-range ferromagnetic correlation, presumably because effects of Mott–Hubbard and Anderson–Mott localization of paramount importance in the case of the narrow d band are implicitly disregarded in the codes developed so far. It thus appears that delocalized or weakly localized valence band holes are necessary to transmit magnetic information between the diluted spins (Dietl *et al*., 2000; Jungwirth *et al*., 2006a). In addition to (Ga,Mn)As, (Zn,Mn)Te:N, and related systems, recent indications of ferromagnetism in p-(Ga,Mn)N (Edmonds *et al*., 2005; Sarigiannidou *et al*., 2006) and p-(Ga,Mn)P (Scarpulla *et al*., 2005) appear to support this conclusion. However, in those and other experimentally relevant cases, nonuniformity associated with hole localization is seen to affect strongly ferromagnetic properties. It is still

to be found out experimentally whether nitrides, oxides or diamond containing 5% of randomly distributed magnetic impurities and more than 3×10^{20} valence band holes/cm^3 show ferromagnetic ordering above the room temperature.

Spin Engineering in Quantum Well Structures

Roberto C. Myers and Arthur C. Gossard
University of California, Santa Barbara, CA, USA

1 INTRODUCTION

The band engineering afforded in heterostructures (Kroemer, 2001) can be tailored at monolayer length scales by using layer-by-layer growth techniques, such as molecular-beam epitaxy (MBE) (Gossard, 1986). Depositing a thin ($\sim$10–100 Å) narrow band-gap material within a wider band-gap material confines band electrons in one dimension at length scales at which this confinement quantizes the wave functions, energy levels, and band structure. These quantum wells (QWs) are essential components in countless optoelectronic devices, such as QW laser diodes, avalanche photodiodes, quantum cascade lasers, and high electron mobility transistors to name a few. In addition to modern device application, QWs have been at the forefront of condensed matter research, providing systems in which band structure, density of states, carrier density, and confinement energy are adjustable.

Recently, the possibility of utilizing the spin of electrons for additional or fundamentally new device functionality, spintronics, has sparked a broad research effort in semiconductors. QWs offer a unique means for controlling the interactions between free carrier spins and localized magnetic-ion or nuclear spins and have the advantage of a high level of technological versatility via advanced growth techniques like MBE. Additionally, QWs have advantageous optical properties for probing and polarizing spin. In spin-LEDs, for example, the degree of circular polarization of electroluminescence from QWs is used as a probe of spin-polarized current through these devices, which is made possible by the unique spin-sensitive optical selection rules.

We review recent developments in semiconductor spintronics, in which electric and magnetic fields are used to polarize, orient, and couple quantum-confined spins. Heterostructure band engineering is used to modify the spin-dependent terms in the Hamiltonian of carriers confined to QWs. This is accomplished in nonmagnetic semiconductors by exploiting the dependence of the spin-orbit interaction on the effective band gap, which is modified by chemical composition and quantum confinement. Vertically biased QWs provide electronic control of the spatial position of carrier wave functions in QWs. Such carrier shifting modifies the spin-dependent terms in the Hamiltonian owing to g-factor gradients or local exchange interactions in magnetically doped QWs. High-frequency modulation of these interactions can be used *in lieu* of an external transverse magnetic field to resonantly manipulate electron and nuclear spins. These techniques are applied in magnetic structures, where the strong exchange interaction between local moments and band electrons massively enhances the energy of the spin interactions compared with nonmagnetic wells. The intrinsic

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

coupling of magnetic and carrier spins can be tailored in QWs to engineer exchange effects through modulation doping or kinetic confinement effects. Increasing the hole carrier density in magnetic wells results in the creation or enhancement of ferromagnetism, while confinement energy modifies the exchange interactions due to band mixing.

2 *g*-FACTORS IN QUANTUM WELLS

2.1 Electron *g*-factor

Band structure strongly alters the spin-orbit interaction in semiconductors QWs. The change in band structure between QW and barrier materials leads to a change in the effective g-factors. Figure 1(a) plots g-factors as a function of band gap for a number of semiconductors and their alloys (Madelung, 2004; Kosaka *et al*., 2001), the traditional map of band gap versus lattice constant is plotted in Figure 1(b), and the g-factor versus lattice constant is in Figure 1(c). The spin splitting between spin-up and spin-down electrons ($\Delta E_{\uparrow\downarrow}$) per unit of magnetic field is also plotted in Figure 1(a), $\Delta E_{\uparrow\downarrow} = g\mu_B B$, showing the range of conduction-band spin splittings possible in these systems, where μ_B is the Bohr magneton and B is the applied magnetic field. The sign change of $\Delta E_{\uparrow\downarrow}$ corresponds to a change in orientation of the electron spin ground state with magnetic field, with electron spins pointing opposite the field when $g > 0$ ($\Delta E_{\uparrow\downarrow} > 0$) and spins pointing parallel with the field for $g < 0$ ($\Delta E_{\uparrow\downarrow} < 0$). The origin of the sign and magnitude change of the effective g-factor for electrons in bulk crystals is the spin-orbit interaction and interband mixing (Roth, Lax and Zwerdling, 1959). Following from a perturbative treatment in k·p theory, the following expression describes the effective g-factor (Hermann and Weisbuch, 1977),

$$g = g_0 - \frac{2}{3}\left(\frac{2p_{sp}^2}{m_0}\right)\frac{\Delta}{(E_g[E_g + \Delta])} \qquad (1)$$

where $g_0 \sim 2.002$ is the g-factor for free electrons, p_{sp} is proportional to the conduction and valence band mixing, and Δ is the spin-orbit splitting of the valence band (spin-split-off band). Equation 1 explains, for example, why wider band-gap materials, such as GaN and ZnO exhibit g-factors close to the free electron value ($\sim$2) and why narrow band-gap semiconductors exhibit negative g-factors, such as GaAs (~ -0.44) and InAs (~ -15). Further, the unusually large and negative value of the conduction-band electron g-factors in InSb (~ -51) and InAs are due to the large Δ in these materials. Alloying semiconductors provides one route for engineering g-factors. In GaAs, by alloying with Al the conduction-band g-factor can be increased from -0.44 in pure GaAs to $+0.6$ in $Al_{0.4}Ga_{0.6}As$ (Chadi, Clark and Burnham, 1976; Weisbuch and Hermann, 1977). It was also shown that alloying GaAs

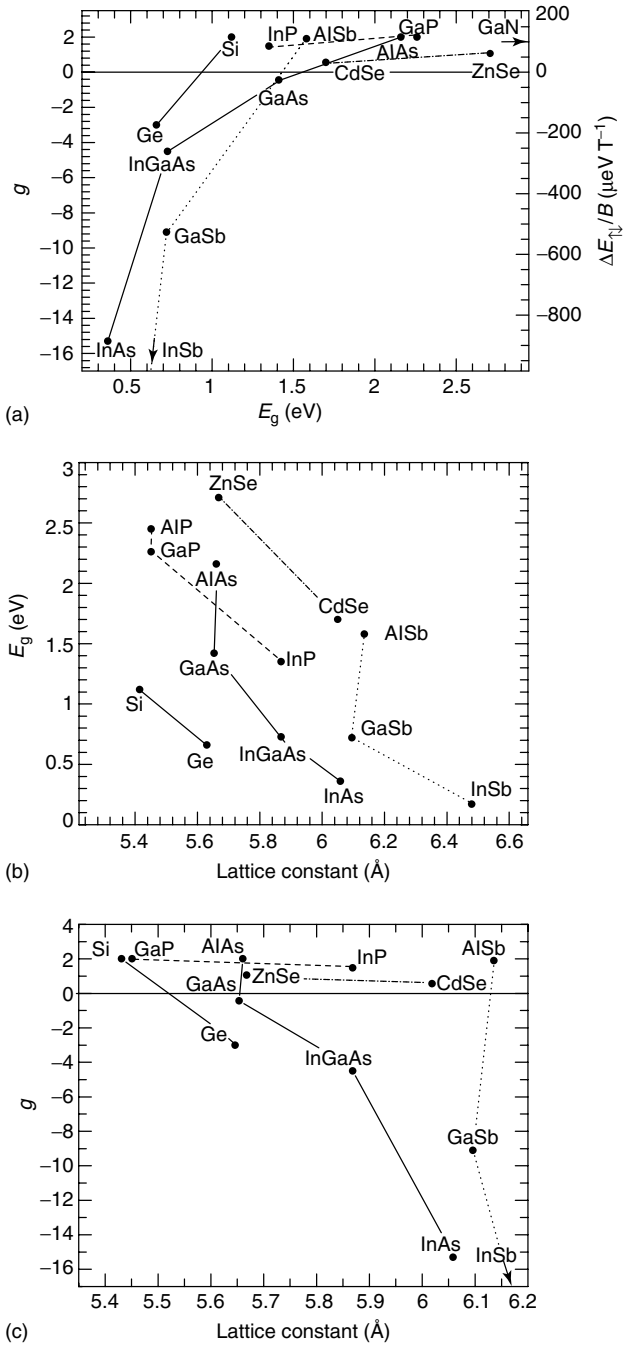

Figure 1. (a) Summary of electron g-factors versus band gap in several semiconductors. Lines connect alloy systems. The corresponding spin splitting in the conduction band is plotted in the right vertical axis per unit of magnetic field. (b) Band gap versus lattice constant for several semiconductors. (c) Electron g-factor versus lattice constant. (Data from Madelung, 2004; Kosaka *et al*., 2001 and references therein.)

with In decreases the g-factor from -0.44 to -0.8 in $In_{0.1}Ga_{0.9}As$ (Weisbuch and Hermann, 1977) and reaches -4.07 in $In_{0.53}Ga_{0.47}As$ lattice matched to InP (Kowalski, Linke and Omling, 1996). An additional modification of g-factors exists in QWs, where spatial confinement of carriers along the growth direction increases the effective band gap (Ivchenko and Kiselev, 1992). The simple substitution of $E_g \rightarrow E_g^*$ in equation (1) provides a rough estimate for the effective g-factor in QWs.

Optical measurements of electron g-factors in a number of QW systems experimentally demonstrate the effect of confinement on carrier spin splittings. Snelling *et al.* used measurements of polarization-resolved photoluminescence (PL) in the Voigt geometry–the Hanle effect–to extract effective electron g-factors and spin lifetimes in GaAs–$Al_xGa_{1-x}As$ QWs (Snelling *et al.*, 1991). These measurements demonstrated that for Al concentrations of 30%, QW width modifies the g-factor from negative values in wide wells to positive values in narrow wells and an effective $g = 0$ for widths near 5.5 nm. These time-averaged measurements were later confirmed by optical measurement of electron spin dynamics in the time domain of similar structures using the technique of time-resolved Kerr or Faraday rotation (Malinowski and Harley, 2000; Poggio *et al.*, 2004; Myers *et al.*, 2005b). Note that such measurements only provide information about the magnitude of the g-factor and not its sign. Figure 2 plots the effective electron g-factor and $\Delta E_{\uparrow\downarrow}$ from (Snelling *et al.*, 1991; Malinowski and Harley, 2000; Poggio *et al.*, 2004; Myers *et al.*, 2005b) showing the wide range in sign and magnitude available in GaAs–AlGaAs and InGaAs–GaAs QWs.

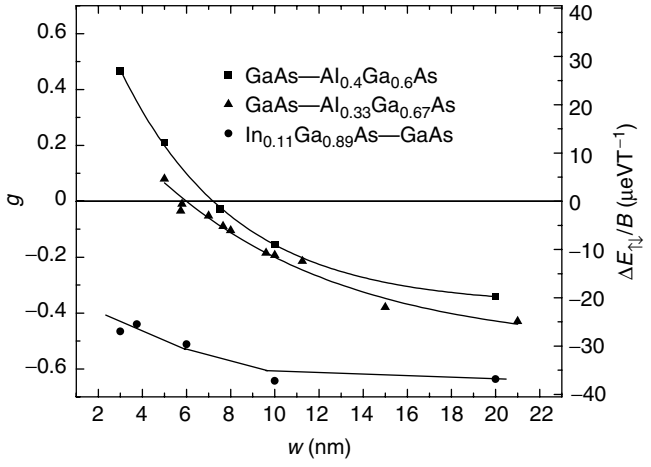

Figure 2. Effective in-plane electron g-factors in some III–V quantum wells plotted as a function of well width (w). (Data reproduced from Snelling *et al.*, 1991; Malinowski and Harley, 2000; Poggio *et al.*, 2004; Myers *et al.*, 2005b.)

2.2 Hole *g*-factor

The energy landscape for electron spins in the valence band is more complex than for the conduction band due to the strong spin-orbit interaction and band mixing of the heavy, light, and spin-split-off bands. In QWs, the degeneracy of the heavy and light hole bands is lifted due to symmetry breaking from confinement and/or strain, whereby the heavy hole band becomes the ground state for holes. The label of these valence bands becomes somewhat of a misnomer in QWs since the heavy hole band in bulk becomes lighter in QWs (larger d^2E/dk^2) and the light hole band becomes heavier (smaller d^2E/dk^2). Away from $k = 0$, the bands therefore cross and result in strong mixing. This results in an anisotropy of the angular momentum that pins the heavy hole spin (3/2) parallel to the growth axis and light hole spin (1/2) perpendicular to the growth axis (Martin *et al.*, 1990).

Polarization-resolved PL was used to measure the Zeeman splittings in GaAs–AlGaAs and InGaAs–GaAs QWs (Snelling, Blackwood, McDonagh and Harley, 1992; Traynor, Harley and Warburton, 1995). From these excitonic spin splittings, the g-factor for heavy holes and heavy hole excitons were extracted. In such experiments, the g-factor of the exciton is defined as the sum of the hole and electron g-factors, which implicitly assumes that exciton binding and electron–hole exchange coupling does not significantly modify the g-factor. In the GaAs–AlGaAs system, heavy hole g-factors undergo a similar sign change as does the electron g-factor near 5.5 nm well width. In the GaAs–AlGaAs system, however, the complexity of the valence band results in nonlinear Zeeman splittings at high magnetic fields making precise determination of the hole g-factors difficult. Usually, the short spin lifetimes ($\sim$110 fs in GaAs) (Hilton and Tang, 2002) of hole spins in bulk semiconductors renders it inaccessible in the time domain, resulting from the fourfold degeneracy of the valence band at $k \sim 0$. However, the degeneracy lifting of the heavy and light hole bands in QWs, discussed in the preceding text, increases the hole-spin lifetime (Uenoyama and Sham, 1990). Measurements of polarization-resolved PL at zero field have shown hole-spin lifetimes of up to 1 ns in 7.5 nm GaAs–$Al_{0.33}Ga_{0.67}As$ QWs (Roussignol *et al.*, 1992). In n-doped QWs of GaAs–AlGaAs, time-resolved/polarization-resolved PL was used to measure the spin precession of optically injected heavy holes in a transverse field, allowing for the observation of heavy hole-spin precession with lifetimes up to 700 ps (Marie *et al.*, 1999). Surprisingly, hole-spin procession has not been observed in almost identical samples using the technique of time-resolved Kerr rotation, where only electron spin precession has been observed (Malinowski and Harley, 2000; Poggio *et al.*, 2004; Myers *et al.*, 2005b). The difference in Fermi level is a possible explanation since the sensitivity of these techniques

changes depending on the density of states. PL is sensitive only to nonequilibrium spin polarization that is optically injected, whereas Kerr and Faraday rotation are sensitive to any spin polarization. It should also be considered that sample-to-sample variation could alter the relaxation processes, especially in samples where both electron and hole g-factors change in sign and magnitude with small changes in well width.

2.3 *g*-factor anisotropy in quantum wells

Quantum confinement alters the g-factor ($g_\parallel$) parallel and perpendicular to the growth axis ($g_\perp$) leading to anisotropic spin splittings (Ivchenko and Kiselev, 1992). This results from the anisotropy inherent to the valence band, where the heavy and light hole bands are split in QWs. Such a splitting affects the anisotropy of both holes and electrons. Heavy hole spins are pinned along the growth axis, while light holes align perpendicular to it, and consequently the g-factors have large anisotropy. The anisotropy of the hole g-factors in QWs has been measured in GaAs–AlGaAs QWs. The g-factors parallel to the growth axis for heavy holes vary from about -2 to $+1$ with QW width as measured from the Zeeman splitting in the Faraday geometry (Snelling, Blackwood, McDonagh and Harley, 1992). The in-plane heavy hole g-factor is more than 10 times smaller, $\sim$0.03 as measured from hole-spin precession in a transverse field (Marie *et al*., 1999) (Voigt geometry), reflecting the strong pinning of heavy hole spins along the growth axis.

The effective band gap has an anisotropy depending on whether the band gap from the light hole or heavy hole is considered. Following from equation (1), the electron g-factor is therefore anisotropic in QWs depending on the splitting between the heavy and light hole bands. Optically detected magnetic resonance (ODMR) was used to measure the anisotropy of the electron g-factor in single–sided modulation p-doped InGaAs–InP QWs (Kowalski *et al*., 1994). In the bulk limit of $In_{0.53}Ga_{0.47}As$, the g-factor was measured to be isotropic with $g \sim 4$. In QWs, the anisotropy increases as the well width narrows, which is plotted in Figure 3. In the narrowest wells measured the ratio, $g_\parallel/g_\perp = 4$. Strain was also modified by changing the concentration of Ga while maintaining the same QW width. Both $g_\parallel$ and $g_\perp$ were modified by the change in strain; however, the ratio of the two remained roughly constant, suggesting that the g-factor anisotropy was strain independent. Similar measurements of g-factor anisotropy by angle-dependent time-resolved Kerr rotation in strained InGaAs–GaAs wells and in unstrained GaAs–AlGaAs wells confirm the strong g-factor anisotropies owing to quantum confinement and weaker dependence on strain (Malinowski and Harley, 2000; Sih *et al*., 2004; Salis, Awschalom, Ohno and Ohno, 2001).

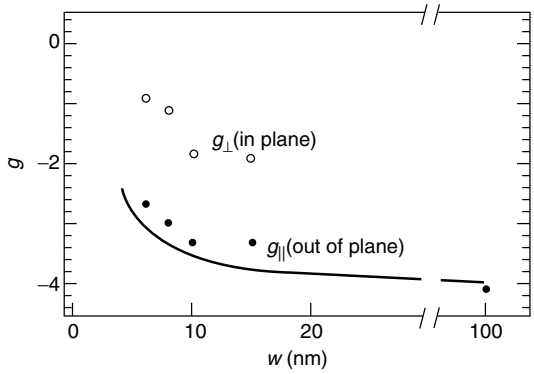

Figure 3. Anisotropic electron g-factor in $In_{0.53}Ga_{0.47}As$–InP quantum wells measured at a temperature of 1.6 K. The g-factor parallel to the growth axis, $g_\parallel$ (solid circles), and perpendicular to the growth axis, $g_\perp$ (open circles), are plotted as a function of well width (w). (Reproduced from Kowalski *et al*., 1994.)

Electron spin precession in a transverse magnetic field is altered by g-factor anisotropy. Since the g-factor is a tensor, the Larmor frequency (Ω_L) gains vector dependence. It is necessary to define the spin precession vector, $\mathbf{\Omega}_\mathrm{L} = \hat{g}\mu_\mathrm{B}\mathbf{B}/\hbar$, which defines the frequency and axis about which electron spins precess. The g-factor anisotropy is responsible for an enhancement of dynamic nuclear spin polarization (DNP) (Salis, Awschalom, Ohno and Ohno, 2001). In a later section, we discuss how these anisotropies can be controlled with a vertical bias leading to a new form of electron spin resonance (ESR) based on manipulation of $\mathbf{\Omega}_L$ through the g-tensor.

3 EXCHANGE INTERACTIONS IN MAGNETIC QUANTUM WELLS

In addition to the spin-orbit interaction, magnetically doped QWs contain the exchange interaction between carriers and localized magnetic-ion spin. In dilute magnetic semiconductor (DMS) theory, the exchange interaction appears as a δ-function-like operator centered on the magnetic-ion impurities in the crystal, which usually consist of transition-metal (TM) ions occupying cation sites. This approximation is successful at modeling a wide range of magnetic semiconductor systems, most notably the $II_{1-x}TM_xVI$ systems (Dietl, 1994). Here, the exchange-induced spin splitting between spin-up and spin-down electrons is given as

$$\Delta E_{\mathrm{s-d}} = -xN_0\alpha\langle S_\mathrm{z}\rangle, \quad \Delta E_{\mathrm{p-d}} = xN_0\beta\langle S_\mathrm{z}\rangle \qquad (2)$$

where x is the concentration of TM impurities, N_0 is the cation density, $\langle S_\mathrm{z}\rangle$ is the projection of the 3d electron spins of the TM ions along the applied field B_z, and $\alpha(\beta)$ is

the s–d (p–d) exchange parameter for conduction (valence) band electrons. The 3d electron spins of the TM ion usually maintain a stable configuration in semiconductors with constant g-factor, for example, Mn^{2+} in II–VI maintains $g \sim 2$ and spin $-5/2$. Thus $\langle S_z \rangle$ is known through the magnetic moment of the TM, and for high enough x, the magnetic moment is measurable by magnetometry. By this token, the magnetic field dependence of the exchange terms, $\Delta E_{s,p-d}$, simply tracks the magnetic moment of the TM, such that in paramagnetic semiconductors the carrier spin splitting will follow a Brillouin function and exhibit a hysteresis loop in a ferromagnetic semiconductor.

An important distinction in the definition of x is made between the case for bulk or QW DMS. In QWs, the spatial confinement for carrier wave functions along the growth axis leads to a modification for the effective exchange splitting. This can be understood from equation (2) as a modification of the effective TM concentration experienced by carriers confined to the QWs, such that the effective x is equal to the overlap integral of the carrier probability density $|\psi_{s,p}|^2$ with the TM concentration profile along the growth axis (z).

The exchange interactions tend to have energy scales with orders of magnitude larger than the spin-orbit or hyperfine interactions, and in the case of ferromagnetic semiconductors, they have a strong hysteretic low-field response. Thus, in principle, magnetic semiconductors are more ideal candidates for a practical semiconductor spintronics. In practice, magnetic doping of semiconductors contains many unique challenges owing to the increased complexity of the physical interactions and to the unintentional formation of crystallographic defects.

3.1 II–VI magnetic wells

In II–VI DMS, magnetic impurities are electrically inert, and the solubility of these impurities is relatively high; for example, 10% Mn in ZnCdSe is easily attainable while maintaining high optical quality. These systems enjoy a long and successful history in the literature including the engineering of spin interactions via quantum confinement in II–VI DMS QWs (Awschalom and Samarth, 1999). Giant Faraday rotations, the high solubility of magnetic impurities, and the large energy scale of the resulting exchange splittings enabled these structures to be ideal test systems for confinement and exchange interactions.

Since TM doping usually increases the band gap in II–VI materials, magnetic QWs can be constructed by simply doping the barrier (Gunshor, Kolodziejski, Nurmikko and Otsuka, 1988). In this case, exchange overlap between carriers in the well and magnetic impurities in the barrier occurs through the penetration of the wave function into the barrier, leading to relatively small x values as compared to bulk DMS alloys. Alternatively, magnetic ions can be doped directly in the well. This can be accomplished, for example, by digital doping submonolayers of MnSe layers into ZnSe–ZnCdSe square QWs (Crooker *et al*., 1995). By changing the thickness and position of the digital MnSe layers within a QW, the effective x values are significantly increased, leading to giant Faraday rotations as large as $\sim 10^7$ deg cm^{-1} T^{-1}. Finally, uniform magnetic doping in both QWs and barriers is possible in CdMnTe–CdMnMgTe, where the exchange constants in both the QW and Mg containing barriers are identical (Mackh *et al*., 1994). The uniform magnetic doping profiles in these structures allow for reliable measurements of the effects of quantum confinement on the exchange parameters (Mackh, Ossau, Waag and Landwehr, 1996; Merkulov *et al*., 1999) discussed in later sections.

3.2 III–V magnetic wells

Although most work in magnetic QWs, to date, has been limited to II–VI paramagnetic DMS systems, III–V magnetic semiconductors offer the prospect of ferromagnetic interactions. Most notably, $Ga_{1-x}Mn_xAs$ ($0.01 < x < 0.08$) grown by MBE exhibits ferromagnetism in the bulk phase (Ohno *et al*., 1996; Ohno, 2002) with Curie temperatures as high as $\sim$150 K reported after postgrowth annealing (Ku *et al*., 2003; MacDonald, Schiffer and Samarth, 2005). Unlike for the case of II–VI, Mn doping in GaAs is electronically active, such that a Mn ion occupying a Ga site acts as an acceptor providing a free hole that takes part in long-range ferromagnetic interaction between Mn-ion spins (Jungwirth *et al*., 2006). Unfortunately, the solubility of Mn in GaAs is small at high substrate temperature ($\sim$580 °C) such that GaMnAs is usually grown at $\sim$250 °C in order to attain high enough Mn densities for ferromagnetism ($\sim$5%). At these temperatures and Mn-doping levels, growth defects such as As antisite (As_{Ga}) and interstitial Mn (Mn_I) are incorporated at high concentrations. Subsequently, electronic and optical performance is severely reduced in comparison to high-temperature grown GaAs. Despite this constraint, several recent experiments in quantum-confined GaMnAs structures have been successful, all involving unique layer structures and growth conditions.

4 VERTICALLY BIASED QUANTUM WELLS

QWs may have tilted bands owing to internal electric fields from electronic doping, surface depletion, electric-dipole polarization, and band-gap gradients. Applying a vertical

bias to QWs provides a convenient means for controlling the carrier density and band bending within these structures. Thus, wave function position and shape can be controlled with vertical bias. In this section, we describe how vertically biased QW structures can be used to manipulate the spin of electrons and local moments. The g-factor gradient and band profiles are tailored by heterostructure design. Applying a vertical bias shifts the electron wave function into regions of varying g-factor allowing control over the sign and magnitude of the electron spin splitting using an electric field. Spatial control of the electron wave function is also used to selectively polarize and depolarize local nuclear spins via the hyperfine coupling. Finally, by applying a high-frequency vertical bias, electron and nuclear spin can be resonantly modulated and depolarized.

The g-factor will shift with band bending owing to wave function penetration into the barriers. This g-factor gradient in semiconductor QWs provides a means for controlling the effective g-factors by changing the position of carrier wave functions confined to these structures. This effect was observed in a two-dimensional electron gas (2DEG) of GaAs–AlGaAs in which the ESR frequency was measured as a function of gate bias (Jiang and Yablonovitch, 2001). A shift in the ESR frequency corresponding to a change in effective electron g-factor of $\sim$0.003 (change in $\Delta E_{\uparrow\downarrow} \sim 0.17\mu\text{eV T}^{-1}$) was observed due to gate bias. In the square well and 2DEGs, the application of an electric field along the growth axis (gate bias) results in a triangular distortion of the QW, in which case, wave function distortion and energy shifting owing to the quantum-confined Stark effect are the main results. Although the wave function minimum is displaced, penetration into the energetically forbidden barriers remains a small effect.

4.1 Parabolic quantum wells

A convenient band structure for spatial wave function control exists in parabolic QWs, in which the first-order effect of linear band bending (constant electric field) is to shift the parabola's minimum (Salis *et al*., 1997). Since the potential maintains the same curvature under a linear distortion, the electronic wave functions remain undistorted and shift their center position to the new potential minimum (Figure 4a). The wave function position and effective g-factor of holes will also be changed by the vertical bias, but electrically tunable hole-spin dynamics have not yet been observed by the optical techniques discussed here.

4.1.1 Heterostructure design

GaAs–AlGaAs-type parabolic QWs can be grown using MBE digital-alloying techniques. The Al concentration is digitally graded to achieve the desired harmonic oscillator potential along the growth axis (Gossard, 1986; Miller, Gossard, Kleinman and Munteanu, 1984). This is accomplished by shuttering the Al beam to grow a digital alloy (bilayer) in which the thickness of AlGaAs and GaAs are varied to attain the desired average Al concentration throughout the QW region. Each bilayer period is typically $\sim$20 Å, in order for enough GaAs to be grown in each bilayer to maintain purity and smoothness throughout the structure. Concentration grading is possible by analog alloying (Kopf *et al*., 1992), in which the flux of each effusion cell is adjusted by changing its temperature, but has the disadvantage that the effusion cell must be stabilized at each temperature setting during which time the growth is paused for several minutes. Such pauses are undesirable during QW growths since the probability of impurity incorporation increases with wait time. Digital alloys are controlled through shutter timing and, therefore, require no growth interrupts to grade composition.

As seen in Figure 4(b), energy-resolved PL measurements confirm the harmonic shape of the potential since the rich excitonic spectrum shows a large family of equally spaced energy levels. The analytically soluble nature of the harmonic potential allows for the determination of conduction and valence band offsets from these spectra.

To attain significant displacements of the electron wave function in these structures, large electric fields need to be applied across the front- and backgates. This requires the application of DC voltages at which typical backgated structures breakdown (Linfield, Jones, Ritchie and Thompson, 1993). The development of low-temperature (LT) grown GaAs conduction barriers by Maranowski *et al*. allows for the application of untypically large electric fields to GaAs-based heterostructures (Maranowski, Ibbetson, Campman and Gossard, 1995). LT GaAs resistive layers are grown between the active layer and the conducting backgate, usually n + GaAs. At a substrate temperature of 250 °C and in an As overpressure, the excess As incorporates into GaAs at concentrations of $\sim$1–2% ($\sim 10^{20}\,\text{cm}^{-3}$). After annealing such layers at high temperature, metallic As precipitates form creating a highly resistive metal/semiconductor/metal composite (Warren *et al*., 1990), massively reducing leakage currents. Further modification of these layers can be performed to reduce photocurrent leakage. Simply increasing the Al content of the LT layer shifts the absorption edge to higher energy removing the photocurrent while maintaining the highly resistive character of LT GaAs (Poggio *et al*., 2003).

4.1.2 Optical detection of electron spin precession

Electron spin dynamics can be observed in the Voigt geometry, where a static magnetic field is perpendicular to the

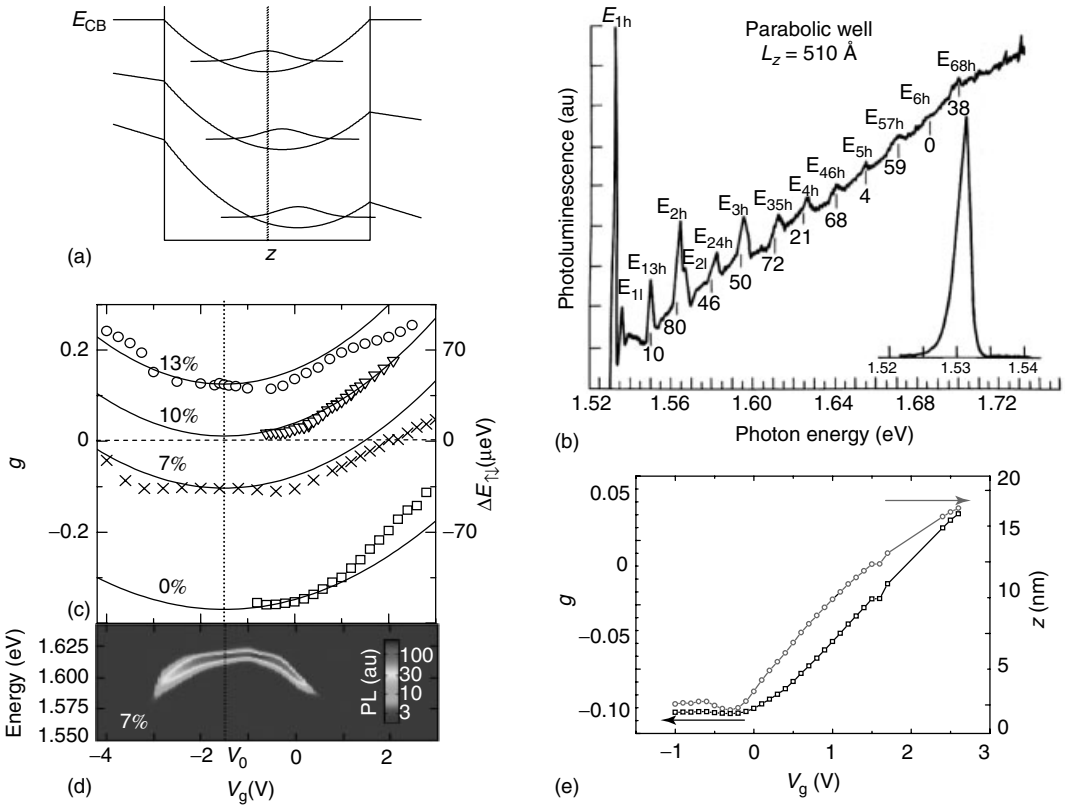

Figure 4. Parabolic quantum wells of GaAs–AlGaAs. (a) Schematic conduction band-edge diagram in a parabolically graded quantum well. The ground state electron wave function displaces along the growth axis (z) with vertical bias. (b) Photoluminescence as a function of excitation energy (PLE) in a 51-nm parabolic quantum well graded from 30% Al in the barriers to 0% in the center of the well. (Reprinted with permission Miller *et al*., copyright 1984, American Physical Society.) (c) g-factor tuning in vertically biased GaAs–$Al_{0.4}Ga_{0.6}As$ parabolic quantum wells from optical measurements of electron spin dynamics via time-resolved Kerr rotation at a temperature of 5 K in a 6 T magnetic field. The wells are 100 nm wide and the percent value represents the concentration of Al in the center of the well. The corresponding spin splitting in the conduction band is plotted in the right vertical axis. (Reprinted with permission G. Salis *et al*., copyright 2001, Nature Publishing Group.) (e) The g-factor versus vertical bias for parabolic quantum well with the corresponding wave function position (z). (Reproduced from Poggio *et al*., 2003.)

optical axis. In this geometry, a circularly polarized excitation pulse excites spin-polarized electrons and holes in the sample that are perpendicular to the magnetic field and thereby induce quantum beating of the spins. The spin dynamics can be optically measured in semiconductor QWs by time-averaged techniques, such as Hanle (Chadi, Clark and Burnham, 1976), or directly in the time domain by using the technique of time-resolved Kerr (or Faraday) rotation (Crooker *et al*., 1996). In the latter technique, the Kerr (or Faraday) rotation of a probe pulse is mapped out in time by controlling the time delay between excitation and probe pulses using a mechanical delay line. The electron spin precession frequency (Ω_L) measures the total spin splitting in the conduction band (along the magnetic field) since $\Delta E_{\uparrow\downarrow} = \hbar\Omega_L = g_z\mu_B B_z$. Hole-spin precession has not been observed in GaAs–AlGaAs using this technique, as discussed previously. In wide parabolic QWs, the weak confinement may not be adequate to increase the hole-spin lifetimes above their usual small values (<1 ps), while electron spin precession is typically observable well into the nanosecond regime.

4.1.3 g-Factor control

Parabolic QWs of GaAs–AlGaAs with LT GaAs (or LT AlGaAs) backgates were used to demonstrate electric-field control of the electron g-factor (Salis *et al*., 2001, 2003). By measuring the electron spin dynamics optically using time-resolved Kerr rotation, the effective electron g-factor was extracted for various bias voltages. Figure 4(c) plots the effective electron g-factor as a function of gate bias in a number of these structures along with the $\Delta E_{\uparrow\downarrow}$. In particular, for samples with 7% Al at the center of the well, g-factor tuning through zero is possible. The g-factor remains constant over a large bias range between 0 and +2 V owing

to exciton binding as evidenced by the loss of PL at biases outside this range, Figure 4(d). PL of these structures displays the quantum-confined Stark effect appearing as a red shift in PL with gate bias, a typical spectroscopic feature of gated QWs (Miller *et al*., 1984). Once the exciton binding between electrons and holes is overcome, PL disappears, electron wave function shifting occurs with less impedance, and the g-factor response to gate bias increases.

The effective electron g-factor in parabolic QWs changes as a function of position along the growth axis because of its dependence on Al concentration (Weisbuch and Hermann, 1977). It can be calculated quantitatively as a weighted average between the electron probability density ($|\psi_s(z)|^2$) and the g-factor at any given position along the QW axis,

$$g^*(z) = \int g(z)|\psi_s(z)|^2 \mathrm{d}z + \Delta g_c \tag{3}$$

where $g^*(z)$ is the effective electron g-factor, $g(z)$ is the g-factor of electrons at each position in the QW due to the local Al concentration, and Δg_c is a phenomenological constant that accounts for confinement effects not included in this simple model. On the basis of the measured values of g^* as a function of gate bias, shown in Figure 4(c), the center position of the wave function (z) can be calculated using equation (3). Figure 4(e) plots the results of this calculation for a 100-nm-wide parabolic QW with 7% Al at the center. The wave function can be displaced ~20 nm at 5 nm V^{-1}.

Recent models of these structures using five-level k·p theory show close agreement with the experiment indicating that the simple picture of g-factor tuning, described above, captures the essential physics (Pfeffer and Zawadzki, 2005).

4.1.4 Shaping nuclear spin profiles

The spatial wave function control in parabolic QWs has also been used to shape nuclear spin profiles (Poggio *et al*., 2003). This experiment exploits the contact hyperfine interaction between electron and nuclear spins to selectively polarize and depolarize nuclear spin profiles at specific positions within a QW (Tifrea and Flatte, 2003). Optically injected spin-polarized electrons in the conduction band of a semiconductor polarize nuclear spins through DNP (Lampel, 1968). This effect only occurs, however, if a longitudinal component of electron spin polarization exists (Salis, Awschalom, Ohno and Ohno, 2001). This is easily accomplished in the Faraday geometry, where the field is parallel to the optical axis, and therefore injects spins parallel to the field. In the Voigt geometry, which is necessary to observe spin precession, spins are, in principle, injected perpendicular to the field and DNP should not be observed since the transverse spin polarization averages to zero. In large magnetic field, the average longitudinal electron spin polarization will not be zero and DNP may occur through the equilibration of electron spins along the field, which were originally polarized transverse to the field (Kikkawa and Awschalom, 2000). Additionally, a direct longitudinal component of spin injection can be created by simply tilting the sample since the excitation beam refracts slightly along the field. In QWs, the g-factor anisotropy leads to a spin precession axis ($\mathbf{\Omega}_L$), which is not parallel with the optical axis (Kalevich and Korenev, 1992). This provides a component of spin injected along the quantization axis and enhances DNP (Salis, Awschalom, Ohno and Ohno, 2001).

If electrons overlap with nuclear spin, the contact hyperfine interaction will modify their spin Hamiltonians, such that the spin splitting is $\Delta E_{\uparrow\downarrow} = \hbar\Omega_L = g_z\mu_B B_z + A_H\langle I_z\rangle$, where A_H is the hyperfine constant and $\langle I_z\rangle$ is the component of nuclear spin along the magnetic field. In analogy to the exchange interaction described in equation (2), the hyperfine constant is weighted by the overlap between electrons and nuclear spin. Thus, control over the electron probability density, as shown in Figure 4(e), will modify the effective strength of the hyperfine term. Nuclear spin profiles were created at arbitrary positions within parabolic QWs by fixing the gate bias, and therefore the electron wave function position, and waiting for 20 min for DNP to saturate. Time-resolved Kerr rotation was used to measure $\Delta E_{\uparrow\downarrow}$ as a function of gate bias once the nuclei were polarized. Subtracting the signal in the unpolarized case allows the extraction of the hyperfine term plotted in Figure 5(a), where the vertical lines plot the center position of the electron wave function during the polarization process (Poggio *et al*., 2003). These nuclear spin profiles can be resonantly depolarized by applying RF to the vertical gates at isotope specific frequencies.

Electrical control over nuclear spin polarization in QWs was recently accomplished in square QWs using a qualitatively different biasing effect than wave function shifting (Sanada *et al*., 2005). In these structures, vertical bias tunes the electron density, which strongly alters the efficiency of the DNP process. Hysteresis in the DNP process has also been reported in similar square QW structures (Sanada *et al*., 2003). Finally, the use of both an RF coil and optical detection of nuclear spin polarization (Poggio and Awschalom, 2005) was used to demonstrate coherent control of nuclear spin in QWs implementing traditional NMR pulse sequences to induce Rabi oscillations (Sanada *et al*., 2006).

4.1.5 Electron spin resonance by g-tensor modulation

So far, we have limited the discussion of electric-field effects to the case of DC bias. It is also possible to apply AC biases to parabolic QWs at frequencies close to the spin

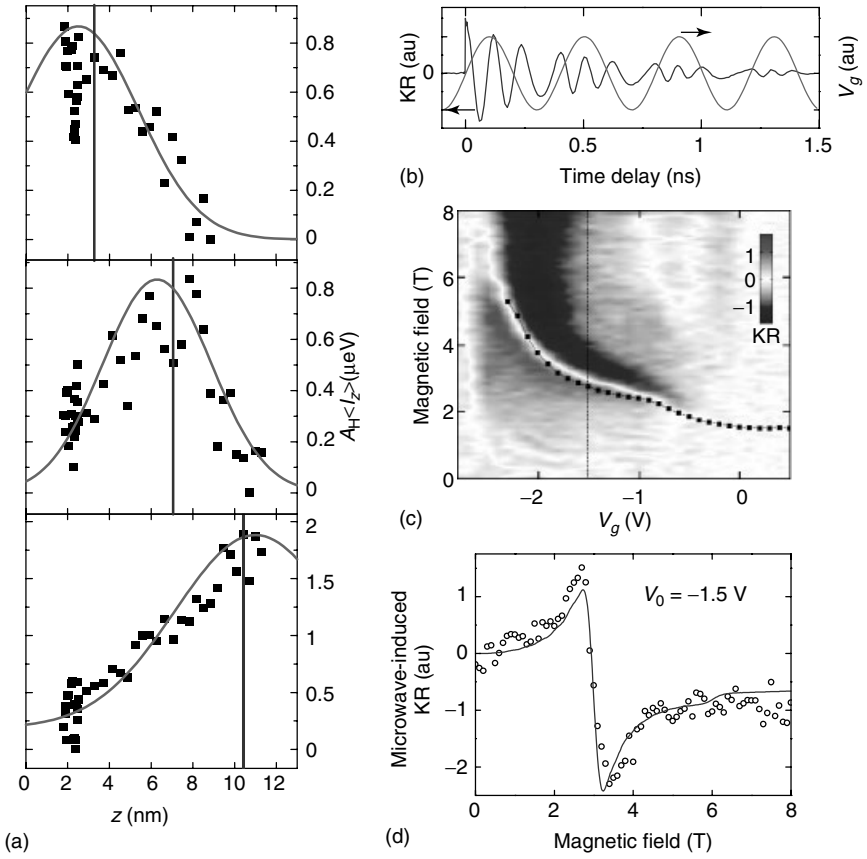

Figure 5. Nuclear and electron spin manipulation in parabolic quantum wells of GaAs–AlGaAs. (a) Spatial profiling of nuclear spin polarization in parabolic QWs of GaAs–AlGaAs at a temperature of 6 K and magnetic field of ∼4 T. The contact hyperfine energy ($A_H\langle I_z\rangle$) due to nuclear spin polarization is plotted along the growth axis (z) with Gaussian fits shown as solid lines. Vertical lines mark the center of the electron wave function when dynamic nuclear polarization was performed. (Part (a) Reproduced from Poggio *et al*., 2003, with permission from the American Physical Society © 2003.) (b) Frequency-modulated electron spin precession due to microwave modulation of the electron g-factor at a temperature of 5 K and magnetic field of 6 T. The microwave signal (2.356 GHz) applied across the front- and backgates is plotted as a sinusoid. (c) The change in electron spin polarization (Kerr rotation) due to the microwave signal (2.66 GHz) as a function of both magnetic field and DC vertical bias. Black squares plot the expected position of g-TMR resonance calculated from the measured anisotropy of the g-factor. (d) Linecut of data in (c) at fixed DC bias showing the resonance structure. precession frequency and resonantly control electron spins (Kato *et al*., 2003). This spin resonance technique, called *g-tensor modulation resonance* (g-TMR), does not require a transverse magnetic field, but makes use of the inherent g-factor anisotropy of QWs. As described in a previous section, the g-factor in a QW is anisotropic because of lateral confinement. Since $g_\perp$ and $g_\parallel$ have different gate bias dependences, electron spins precess about different axes depending on the vertical bias. In gated parabolic QWs, the g-factor anisotropy is modulated by applying AC bias between the front- and backgates, effectively modulating the spin precession vector. Microwave frequency is applied across the front- and backgates of a parabolic QW, while measuring the electron spin precession using time-resolved Kerr rotation. The repetition rate of the laser (∼76 MHz) is used as a reference clock for a frequency tunable microwave amplifier. Thus, nearly gigahertz frequency voltages are applied to the QWs in phase with the laser. Additionally, the laser is operated in a phase-locked loop to maintain a stable repetition rate. Figure 5(b) plots the Kerr rotation as a function of time showing electron spin precession in the presence of ∼2 GHz gate bias. Since the effective g-factor is modulating at ∼2 GHz, electron spin precession is frequency modulated.

When the modulation frequency is brought into resonance with the spin splitting along the quantization axis (g-TMR), electron spins can be tipped either toward or away from the magnetic field. The requirements to observe g-TMR are that the g-tensor must be modulated at the spin-splitting frequency and that the g-factor must be anisotropic. Both criteria are satisfied in these parabolic QW structures. Lock-in amplification was used to measure the microwave-induced

Kerr rotation as a function of magnetic field and an additional DC vertical bias (Figure 5c). The measurements show a clear resonance line that shifts with magnetic field and vertical bias. The position of the resonance matches calculated values (black squares) based on angle-dependent measurements of the g-factor anisotropy. Line cuts at fixed bias voltage (Figure 5d) reveal the shape of the resonance lines and match numerical simulations (solid line).

4.2 Coupled quantum wells

In parabolic QW structures, the electron wave function shifts in a continuous manner. It is also possible to achieve discrete changes in electron position in coupled QWs. These structures consist of adjacent QWs connected by barriers that are thin enough for wave function tunneling to occur (Dingle, Gossard and Wiegmann, 1975). Vertically biased coupled QWs have been used for transition from the spatially direct exciton state, where the exciton resides in one well, to the spatially indirect exciton state, where the exciton is split between adjacent wells (Chen, Koteles, Elman and Armiento, 1987). The resulting change in spatial overlap between the electron and hole drastically alters the transition rates and can be used to modulate absorption (Islam *et al.*, 1987). If the widths of the coupled wells are different, then shifting the electron wave function between wells changes the electron g-factor owing to its strong width dependence (Figure 2).

The electron g-factor was measured in coupled QWs of GaAs–AlGaAs as a function of vertical bias for samples with different tunnel barriers widths (Poggio *et al.*, 2004). Figure 6 plots the g-factors in these structures measured by time-resolved Kerr rotation together with the schematic band-edge diagrams. For uncoupled QWs with a large 20-nm tunnel barrier (Figure 6a), two g-factors are visible over the full bias range corresponding to the different g-factors in the two wells. Tunneling between the wells does not occur within the carrier recombination time. A sharp g-factor transition with vertical bias occurs for a sample with a 6-nm tunnel barrier (Figure 6b), where electron tunneling is incoherent. Finally, strong coupling of the wells is observed in narrow 2-nm tunnel barriers (Figure 6c), where the g-factor is smoothly varied between its value in the two wells.

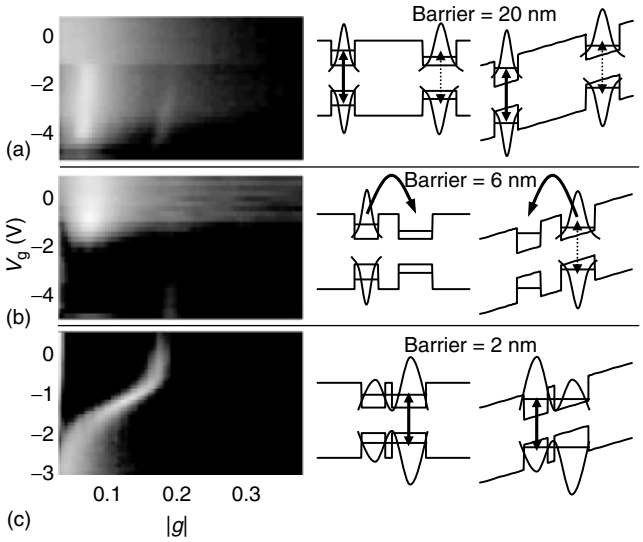

Figure 6. Tuning the electron g-factor in coupled quantum wells of GaAs–$Al_{0.3}Ga_{0.7}As$. The two wells are 7 and 10 nm wide. Color intensity plots the Fourier transform of electron spin precession as a function of vertical bias and g-factor at a temperature of 5 K in a 6 T magnetic field. Schematic band-edge diagrams show the effect of vertical bias for coupled wells with different tunnel barrier widths. Vertical arrows indicate the strong (solid line) and weak (dashed line) photoluminescence transitions and curved arrows show the interwell tunneling. (a) Two distinct g-factors in uncoupled wells with 20-nm-wide tunnel barrier. (b) Sharp g-factor switching for incoherently coupled wells with 6-nm tunnel barriers. (c) Smooth g-factor tuning in coherently coupled wells with 2-nm tunnel barriers. (Reprinted with permission M. Poggio *et al.*, copyright 2004, American Physical Society.)

5 ENHANCEMENT OF MAGNETIC INTERACTIONS IN QUANTUM WELLS

Magnetic doping alters the magnetic field response of $\Delta E_{\uparrow\downarrow}$ from its typical linear field dependence in nonmagnetic structures, to a Brillouin function in paramagnetic structures, and finally showing hysteretic behavior in ferromagnetic structures. Electronic and magnetic doping can be independently engineered in QWs with exchange interactions that are orders of magnitude larger than the spin-orbit induced spin splittings. Confinement also increases the density of carriers near the magnetic impurities, which can have a dramatic effect on the carrier-mediated ferromagnetism. Quantum confinement alters the strength of the exchange interactions extrinsically by increasing the effective TM density experienced by carriers in the wells and intrinsically through more complex kinetic energy effects.

5.1 Vertically biased magnetic wells

The vertical biasing techniques used in nonmagnetic QWs can also be employed in magnetically doped structures to electrically tune the interaction between carrier spin and magnetic-ion spin. The electronic characteristics of magnetic impurities in semiconductors may complicate this task since their associated charges will screen the electric field, damping the effect of bias. This is not a problem in II–VI systems where TM impurities are neutral, but occurs in III–V, for

example, GaMnAs, where the Mn ions act as acceptors. The ionized impurities will screen the electric-field and can act as nonradiative recombination centers. These constraints can be balanced by moving the magnetic layers into the QW barriers or reducing the doping level.

5.1.1 II,Mn-VI parabolic wells

In previous sections, we described the use of digital magnetic doping to achieve large effective magnetic doping densities in II–VI magnetic QWs. This doping technique allows the local placement of magnetic impurities within optically active QWs. Also, we discussed the use of vertically biased parabolic QWs to control the wave function position. Both schemes have been incorporated into parabolic QWs containing local magnetic impurities in which the exchange overlap between carriers in the wells and magnetic impurities can be controlled with vertical bias (Myers *et al*., 2005a). Samples of ZnSe–$Zn_{0.85}Cd_{0.15}Se$ parabolic QWs were grown by MBE. Submonolayers of MnSe were deposited in the center 5 nm of the structures. Electron spin precession at the absorption edge of the QWs was measured using time-resolved Kerr rotation to extract the effective electron g-factor. The inset of Figure 7(a) plots the electron g-factor as a function of vertical bias for a nonmagnetic control sample showing a g-factor shift due to the spatial translation of the electron wave function under vertical bias into regions of varying Cd concentration. For magnetically doped sample, the effective g-factor was increased by an order of magnitude and can be tuned over 400% (Figure 7a, open circles). As the conduction-band exchange term increases, the electron spin lifetime decreases since the spin-flip scattering decoherence mechanism is proportional to the exchange splitting (Crooker *et al*., 1995). At low bias, the exchange overlap is maximized and the spin lifetime is small, whereas at large negative bias when the exchange overlap is minimized the electron spin lifetime increases.

Equally large shifts in the effective g-factor were observed as a function of the optical excitation and probe energy (E_p). As E_p was increased at zero bias, the electron g-factor decreased from 18 to 6 (Figure 7b). This dramatic change was explained as being due to the large difference in exchange overlap, which is due to sublevel filling effects. The wave function ground state has a maximum at the QW center, a position at which the excited state has a node. Estimates of the sublevel spacing and subsequent exchange overlap are consistent with this picture.

In addition to electron spin precession, Mn-ion spin precession is observed in these samples which originates from a spin-flip interaction between optically injected hole spin and Mn-ion spin (Crooker *et al*., 1996). Thus, the amplitude of the Mn-ion spin precessions should be proportional to the exchange overlap between holes and Mn ions, which is significantly altered under vertical bias. At negative bias, the Mn-ion spin precession amplitude was observed to decrease by an order of magnitude and can be explained by the decrease in hole-Mn exchange overlap under negative bias. We have discussed only the effect of exchange interactions on the amplitude of the Mn spin precession. Although Mn-ion spin precession has been observed, the back-action of electron spins on Mn-ion spin splitting has not been observed; the Mn precession frequency always remains constant. Such a shift in the Mn effective g-factor is expected and has been observed, for example, in paramagnetic resonance measurements of n-CdMnTe quantum wells (Teran *et al*., 2003).

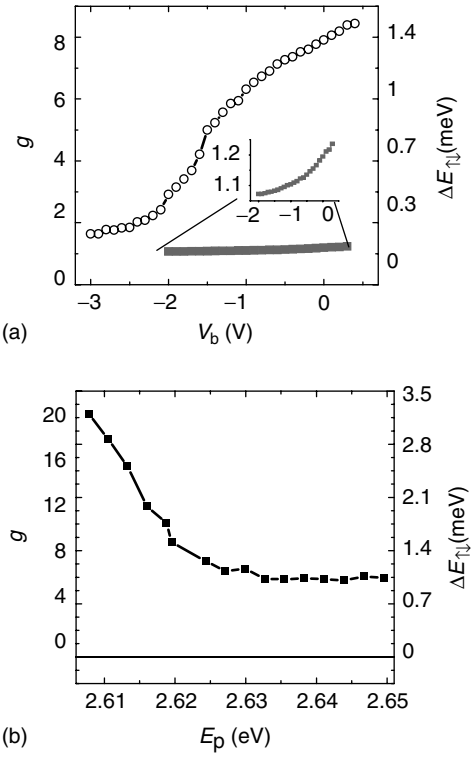

Figure 7. Electrical control of exchange overlap in ZnCdSe–CdSe parabolic quantum wells doped with MnSe. (a) The effective electron g-factor as a function of vertical bias (open circles). The g-factor versus bias in nonmagnetic control samples (closed squares) is enlarged in the inset. (b) Effective electron g-factor as a function of excitation and probe energy (E_p). Corresponding spin-splitting energies are plotted on the right vertical axes. Measurements performed at a temperature of 5 K in a 3 T magnetic field. (Reprinted with permission R.C. Myers *et al*., copyright 2005, American Physical Society.)

5.1.2 III–V wells with a ferromagnetic barrier

In the previous structure, Mn ions are paramagnetic and large magnetic fields (∼10 T) must be applied to fully saturate their moments. Ferromagnetic layers provide lower

saturation field and a hysteretic response. The coupling of ferromagnetic spins to carrier spins in a QW results in strong spin splittings and polarizations at low field. This strategy is advantageous over bulk systems, since QW structures contain an inherent localization of the interactions that can be controlled via heterostructure design. As discussed in previous sections, however, defect control remains a barrier to combine both robust ferromagnetism and high-quality QWs in which spin-sensitive optical or electronic measurements are possible. In the GaMnAs, the level of Mn doping required for ferromagnetism leads to a degenerate hole gas and the incorporation of interstitial Mn defects and As antisites, which limit the optical performance of this material. An alternative approach incorporates submonolayer ferromagnetic layers of MnAs embedded within a GaAs matrix, so-called digital ferromagnetic heterostructures (Kawakami *et al*., 2000). These structures have the advantage that ferromagnetism in the MnAs layers can be independent of the electronic doping in the surrounding GaAs matrix (Johnston-Halperin *et al*., 2003).

Such layers have been incorporated into the top AlGaAs barriers of GaAs QWs, where optical quality in the QW is maintained by combining both the growth of QWs at high temperature with the growth of the magnetic barrier at LT. Design constraints of such hybrid structures dictate that magnetic layers must be grown after the QW layers since high-temperature annealing of the magnetic layers would lead to the formation of Mn-containing second phase defects. Additionally, the ferromagnetic layer must be spaced sufficiently far from the QW to maintain an optical response in the wells, but close enough for coupling effects to be observed.

Polarization-resolved PL in these structures revealed that initially unpolarized photoexcited holes in a GaAs QW become spin polarized opposite to the magnetization of the ferromagnetic barrier (Myers, Gossard and Awschalom, 2004). The optical selection rules in QWs dictate that the spin-polarized holes or electrons will emit circularly polarized photons, thus PL polarization is an indicator of spin polarization. Figure 8(a) shows the circular polarization of the PL emission in the QW, tracking the magnetization of the ferromagnetic layers. A negative vertical bias increases this polarization indicating that its origin is spin-polarized heavy holes coupled through wave function overlap with spins in the ferromagnetic layer. As shown in Figure 8(b) and (c), vertical bias changes the polarization from positive to negative while maintaining the same field response as the ferromagnetic layer. These structures provide a means for electrically controlling spin polarization at low magnetic fields in a QW through wave function overlap.

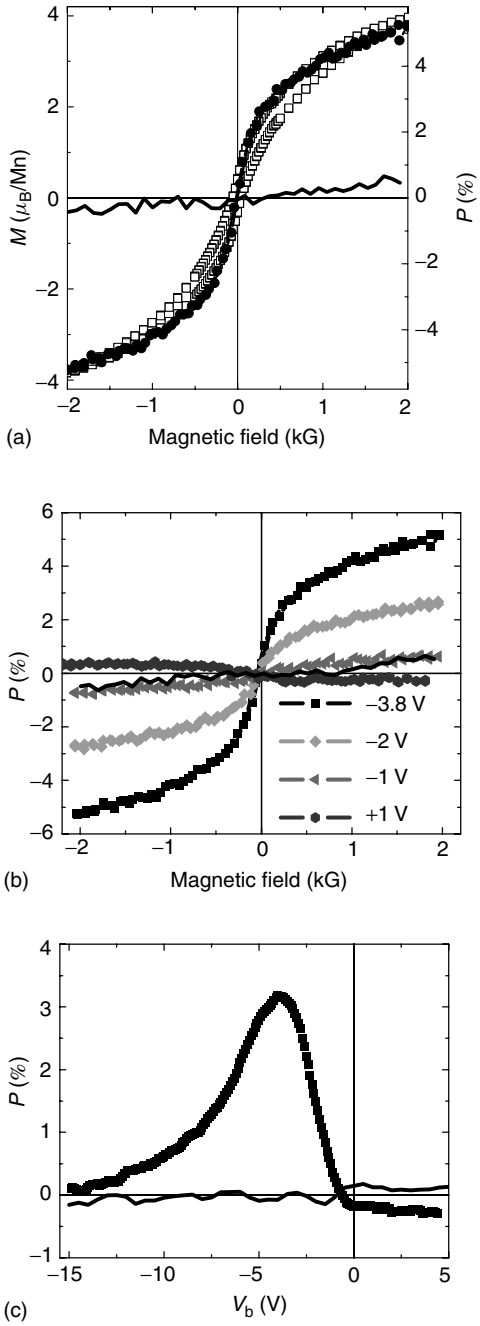

Figure 8. Tunable spin polarization in GaAs–AlGaAs square wells with a ferromagnetic barrier at 5 K. (a) Spin polarization and magnetization as a function of magnetic field (B). Magnetization (M) measured by SQUID magnetometry is plotted in the left vertical axis (open squares). Photoluminescence polarization (P) is plotted in the right vertical axis (closed circles). The P measured in a nonmagnetic control sample is plotted as a solid line. (b) Field dependence of P at various vertical biases for a sample with a ferromagnetic barrier (symbols), and control sample (solid line) in a +1 kGs magnetic field. (c) Vertical bias dependence of P for the sample shown in (b) (solid squares) and for the control sample (solid line). (Reprinted with permission R.C. Myers *et al*., copyright 2004, American Physical Society.)

5.2 Ferromagnetism in modulation doped wells

The inherent coupling of TM spins in II–VI semiconductors is antiferromagnetic (Dietl, 1994). However, upon hole doping, the strong p–d exchange coupling between valence band and magnetic-ion spins enables a long-range ferromagnetic coupling. Here, the itinerant hole spins couple to more than one localized magnetic-ion spin and results in ferromagnetism in both II–VI and III–V systems (Dietl *et al*., 2000). In QW structures, modulation doping may be used to locally increase the hole density over the TM spins and create or enhance the ferromagnetic state.

5.2.1 Ferromagnetic II,Mn-VI wells

As previously discussed, TM doping in II–VI semiconductors is isoelectronic providing no free holes. The direct coupling between magnetic spins is antiferromagnetic, which is observable at high doping levels where these nearest-neighbor interactions dominate. Magnetic spins display paramagnetism when sufficiently diluted. A long-range and hole-mediated ferromagnetic interaction occurs when holes are present. Ferromagnetism has been created in $Cd_{0.976}Mn_{0.024}Te$ QWs by modulation doping holes using specially designed $Cd_{0.66}Mg_{0.27}Zn_{0.07}Te$:N barriers (Haury *et al*., 1997). Figure 9(a) plots the polarization-resolved PL spectra of these QWs at very low magnetic field. A giant Zeeman splitting is observed because of the exchange splitting in the conduction and valence bands (equation (2)). The strong low-field dependence of the spin splitting is indicative of the ferromagnetic state. Quantitative analysis of the field-dependent exchange splitting was used to extract the magnetic susceptibility (χ) as a function of temperature (Figure 9b). The temperature intercept of the inverse susceptibility is the mean-field ordering temperature, essentially the Curie temperature, which is 1.8 K for these structures. In samples without modulation hole doping (open squares in Figure 9b) ferromagnetism is not observed and can be destroyed in the hole-doped samples by illumination (open circles).

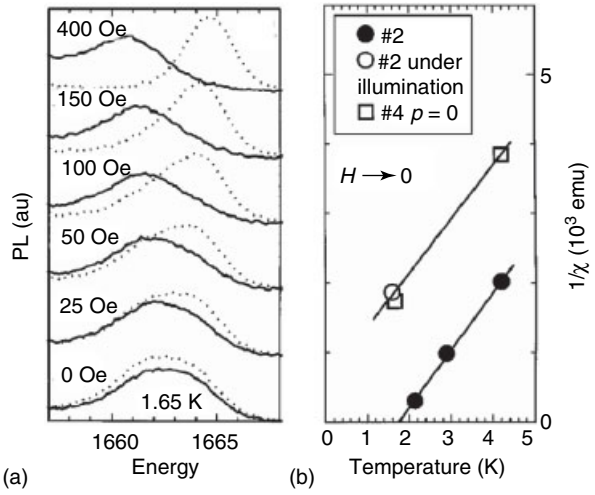

Figure 9. Ferromagnetism in $Cd_{0.976}Mn_{0.024}Te$ quantum wells by modulation hole doping. (a) Polarization-resolved photoluminescence (PL) at 1.65 K. The $\sigma+$ (solid line) and $\sigma-$(dotted line) spectra are plotted at several fields, showing a giant Zeeman splitting at low field indicative of ferromagnetism. (b) Inverse magnetic susceptibility ($1/\chi$) as a function of temperature. Data points were calculated from fits to the field-dependent Zeeman splitting measured by polarization-resolved PL. Data are shown for the modulation hole-doped sample displaying ferromagnetic order (solid circles), for the same sample under white light illumination which destroys the ferromagnetic ordering (open circles), and for a sample without modulation hole doping (open squares). (Reprinted with permission Haury *et al*., copyright 1997, American Physical Society.)

5.2.2 Enhanced Curie temperature in III,Mn-V 2DHGs

The creation of ferromagnetism in II,Mn-VI QWs by modulation hole doping is an impressive demonstration of the controllable coupling between magnetic-ion and free carrier spin in semiconductors. The low ferromagnetic transition temperature, however, makes these structures technologically impractical. Ferromagnetism in GaMnAs is a robust phenomenon, as previously discussed, since Mn acts as an acceptor GaAs providing free holes that mediate the ferromagnetism. Additionally, postgrowth annealing of GaMnAs has been shown to increase the Curie temperature (Ku *et al*., 2003) by diffusing interstitial Mn to the surface that would otherwise compensate holes (Edmonds *et al*., 2004). Thus, GaMnAs is an ideal system for investigating the effects of modulation doping on ferromagnetism.

This strategy has been used in GaAs–AlGaAs two-dimensional hole gases (2DHG) where modulation hole doping in the AlGaAs barrier controls the hole density in the 2DHG which contains a magnetic layer (Nazmul, Sugahara and Tanaka, 2002). Submonolayers of MnAs were incorporated into the 2DHG region using a two-step growth process resulting in the valence band-edge profile shown in Figure 10(a) (Nazmul, Sugahara and Tanaka, 2003a). As discussed previously, such structures contain a design constraint that the substrate temperature cannot be increased after the magnetic layer is grown. Thus the Be-doped AlGaAs barrier and a thin layer of GaAs were grown first at high temperature, while submonolayers of MnAs were deposited within the GaAs 2DHG region at LT. The magnetization of the layers are probed indirectly using the anomalous Hall effect, which is particularly strong in

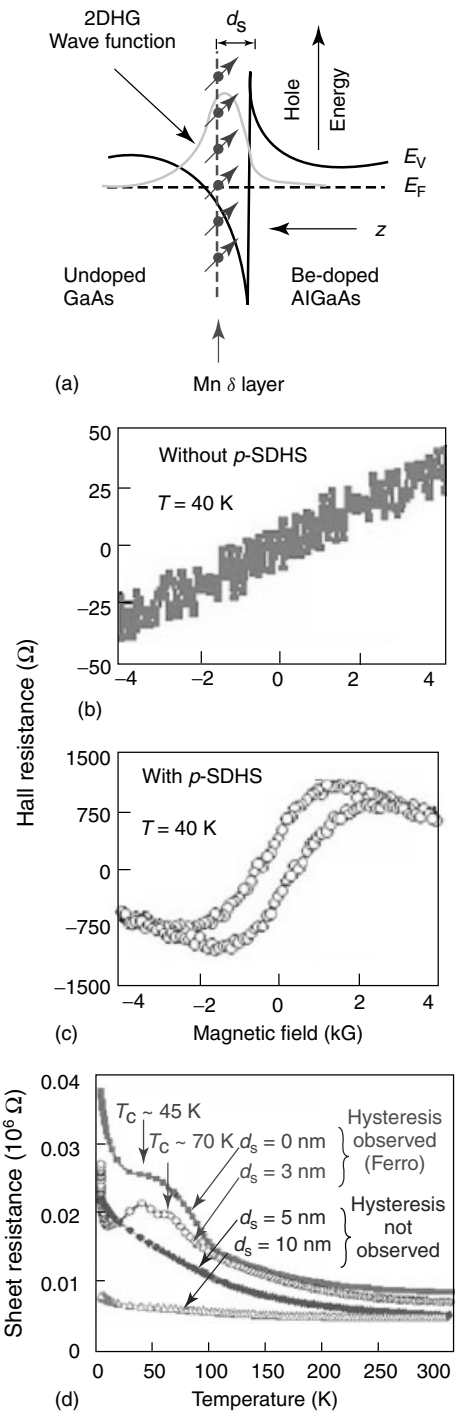

Figure 10. Enhanced ferromagnetism in modulation hole-doped GaAs–AlGaAs two-dimensional hole gases (2DHGs) with MnAs. (a) Valence band edge (E_V) along the growth axis (z) showing the hole wave function, Fermi level (E_F), and position of the Mn ions. (b) Hysteretic field sweeps of the Hall resistance for a sample containing a MnAs layer without hole doping, and (c) for a sample containing hole doping. (d) Resistance as a function of temperature for hole-doped samples with various MnAs positions (d_s) relative to the AlGaAs barrier. (Reprinted with permission Nazmul *et al*., copyright 2003, American Physical Society.)

the GaMnAs system (Ohno, 2002). The Hall resistance in a magnetic layer contains an additional term that tracks the magnetization. Figure 10(b) plots the Hall resistance as a function of field in a sample without modulation hole doping. A hysteresis appears in samples containing modulation doping (Figure 10c) indicating that the MnAs layers are ferromagnetic. Features in the sheet resistance appear near the Curie temperature of the MnAs layer (Figure 10d).

Optimization of the magnetism in these layers has been performed by adjusting the position of the MnAs layers for maximum overlap with the 2DHG. However, postgrowth annealing of the samples leads to the largest increase in Curie temperature (up to 172 K) (Nazmul, Sugahara and Tanaka, 2003b). More recently, the Curie temperature has been further increased in these structures by inverting the 2DHG, such that the p-doped AlGaAs layer is grown after the magnetic layer at LT. After postgrowth annealing, a hysteresis in the Hall resistance was observed up to 250 K, the highest Curie temperature in the GaMnAs system reported to date (Nazmul *et al*., 2005).

The magnetic anisotropy of these layers remains an open question. Hall measurements are performed with the magnetic field applied out of plane. Thus, the appearance of a hysteresis indicates the magnetic easy axis to be out of plane of the film. In submonolayer MnAs layers, the easy axis is typically in plane and shows no hysteresis along the out of plane hard axis (Kawakami *et al*., 2000).

5.3 Kinetic exchange effects in quantum wells

As discussed in a previous section, the conduction-band spin splitting includes both the regular Zeeman splitting plus the exchange interaction,

$$\Delta E_{\uparrow\downarrow} = g\mu_B B + \Delta E_{s-d}, \qquad \Delta E_{s-d} = -xN_0\alpha\langle S_z\rangle \quad (4)$$

The s–d exchange parameter (α) is typically small (0.2 eV) and positive resulting from direct exchange interaction between s-like conduction-band electrons. This contrast with the p–d exchange parameter (β), which is large ($\sim$1 eV) and negative in magnetic semiconductors due to hybridization between p-like valence electrons and the d orbitals localized on the TMs (Dietl, 1994), a mechanism known as *kinetic exchange* (Dietl, 1981; Bhattacharjee, Fishman and Coqblin, 1983). The hybridization occurs due to the virtual transition of electrons from the valence band into d states. The relative strength of these interactions varies with the confinement energy since electrons with larger k values increase their probability of occupying the d states.

5.3.1 II,Mn-VI wells

Quantum confinement has been observed to alter the exchange splittings in II,Mn-VI QWs. Polarization-resolved PL measurements in CdMnTe–CdMnMgTe wells showed a reduction in the exciton exchange splitting of ∼15% compared with bulk (Mackh, Ossau, Waag and Landwehr, 1996). This effect was modeled taking into account the confinement dependence of the p–d exchange parameter, but a full quantitative agreement was lacking (Bhattacharjee, 1998).

Measurements of the conduction-band exchange splitting in these QWs indicated that in addition to a kinetic modification of the p–d exchange term, the s–d exchange term is reduced by quantum confinement by up to 25% of its bulk value (Merkulov *et al*., 1999). Figure 11 plots the normalized s–d exchange parameter in CdMnTe–CdMnMgTe QWs as a function of confinement energy, E_e. The exchange splitting was measured by spin-flip Raman scattering as a function of magnetic field and representative scans are plotted in the inset of Figure 11. The data were modeled (line in Figure 11) by modifying the theory in (Bhattacharjee, 1998) to include the effect of band mixing and virtual transitions, that is, kinetic exchange, of conduction-band electrons into d states. The s–d exchange parameter decreases with confinement mostly because the conduction electrons get larger k values and mix with the valence band. The contribution of the valence band exchange parameter is negative since these p-like states hybridize readily with the magnetic d states, that is, p–d is large and negative.

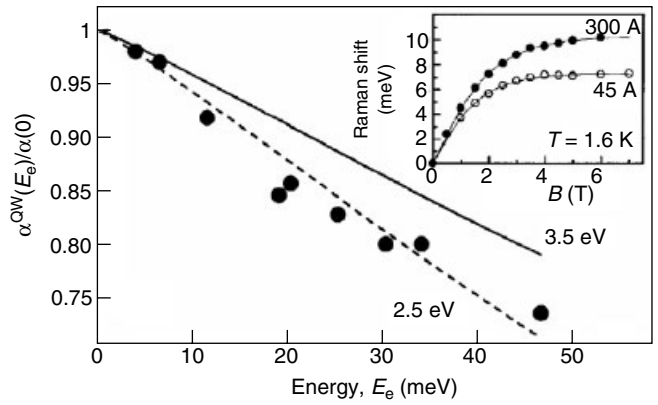

Figure 11. The conduction-band exchange parameter (α) as a function of the confinement energy in a $Cd_{0.98}Mn_{0.02}Te$–$Cd_{0.876}Mn_{0.014}Mg_{0.11}Te$ quantum well. Inset: Magnetic field dependences of the spin-flip Raman shifts in two quantum wells of different width. Fits to these data were used to extract α plotted as solid circles in the main figure. Solid and dashed lines plot calculations based on a kinetic exchange model. (Reprinted with permission Merkulov *et al*., copyright 1999, American Physical Society.)

5.3.2 III,Mn-V wells

The exchange parameters in III,Mn-V semiconductors, in particular GaMnAs, are usually not accessible using traditional band-edge optical techniques because of the high defect densities inherent to these materials. Such measurements have recently become possible in GaMnAs–AlGaAs QWs grown by MBE with low doping levels ($10^{17}-10^{19}\,cm^{-3}$) at intermediate substrate temperatures (Myers *et al*., 2005b). Electronic and structural measurements indicate that most of the Mn resides on substitutional Ga sites (Poggio *et al*., 2005). Time-resolved Kerr rotation measurements were used to measure the total conduction-band spin splitting for a range of Mn-doping concentrations and QW widths. Using equation 4, the effective exchange constant ($xN_0\alpha$) was extracted based on measurements of the g-factor in identical nonmagnetic samples (Figure 2). Figure 12(a) plots the effective exchange constant as a

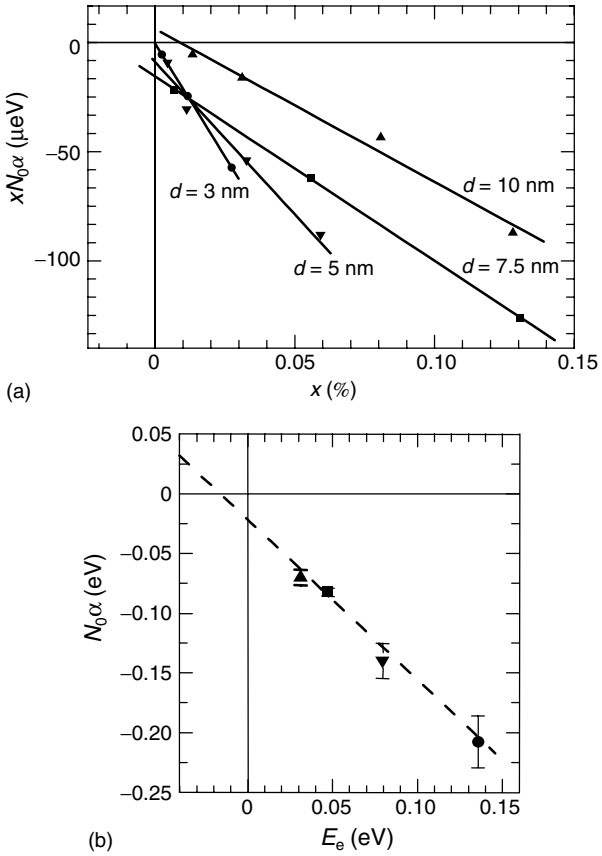

Figure 12. The conduction-band exchange constant in $Ga_{1-x}Mn_xAs$–AlGaAs quantum wells. (a) The conduction-band exchange splitting ($xN_0\alpha$) as a function of x. Linear fits connect data from wells of the same width. (b) The exchange parameter ($N_0\alpha$) as a function of electron confinement energy with a linear fit (dashed line). Data points correspond to linear fits in (a). (Reprinted with permission R.C. Myers *et al*., copyright 2005, American Physical Society.)

function of Mn density demonstrating that the exchange parameter increases linearly with Mn-doping density, while the slope varies with QW width. This indicates that the II,Mn-VI exchange model (equation (4)) is valid in the GaMnAs system, and that quantum confinement appears to alter the exchange parameter as in II,Mn-VI QWs. Figure 12(b) plots the exchange constant as a function of confinement energy for electrons in GaMnAs QWs. Surprisingly, the exchange parameter is negative in all the QWs in contrast to II–VI magnetic semiconductors. However, the confinement leads to a negative contribution to the exchange parameter, the same as observed in (Merkulov *et al*., 1999). Measurements in quantum wells with lower barriers confirms this trend (Stern *et al*., 2007). Recent theoretical investigations predict the confinement-induced negative s–d exchange coupling in GaMnAs QWs (Dalpian and Wei, 2006).

6 SUMMARY

In semiconductor QWs, a control over the interactions between a variety of spin systems are possible, which are unfeasible in the bulk. The atomic layer precision of MBE allows for a precise engineering of g-factor sign and magnitude by quantum confinement and band engineering. In vertically biased wells, the controllable band bending spatially shifts carrier wave functions, thereby modulating their spin splitting through g-factor gradients and through local interactions with nuclear spin. Continuous shifting of the wave function is possible in parabolic QWs, while tunneling between coupled square wells provides more discrete changes in the wave function position. Adding a high-frequency component to the vertical bias allows for resonant control of spin, such as g-TMR and nuclear spin resonant depolarization.

The measurement of these effects relies on the ability to resolve electron spin precession, through ultrafast optical spectroscopy, which in turn places requirements on the transverse electron spin lifetime. Despite much theoretical and experimental work, engineering electron spin lifetimes in QWs remains mostly an empirical endeavor of trial and error. This arises due to competing variables that may enhance or limit spin lifetime, such as electronic doping (either modulation or direct doping), Fermi level, and carrier temperature. This may offer some explanation for the discrepancy between time-resolved Kerr (or Faraday) rotation measurements and time-resolved PL in which hole-spin precession has and has not been observed in nominally identical structures, respectively. Since hole wave functions shift with vertical bias, g-factor tuning of hole spin must also occur. Engineering structures for improved hole-spin lifetimes by carrier doping, strain, or confinement, may allow these hole-spin effects to become observable.

Spin splittings in nonmagnetic structures tend to be of the order of $10\,\mu\mathrm{eV\,T^{-1}}$ and this energetic fragility usually requires low sample temperatures and high magnetic fields to observe the effects. Magnetically doped semiconductors offer orders of magnitude larger and more robust spin splittings that in principle can scale to technologically practical temperatures and magnetic fields. In vertically biased magnetic QW structures, analogous to those used in nonmagnetic wells, such an enhancement of the spin interactions has been observed. In these structures, the exchange overlap between carrier and magnetic-ion spins is electrically controlled, which changes the spin polarization and spin dynamics of carriers in the wells. In principle, the manipulation of Mn-ion spins through electron or hole-spin polarization should be possible; so far only the reverse has been observed. These techniques contrast with indirect spintronic devices such as spin-LED structures, where magnetic layers are remote from the optically active region and measurements of direct spin couplings are not possible.

Engineering the carrier density and quantum confinement in QWs provides, also, a means to alter or enhance the intrinsic interactions between free carriers and magnetic ions. Modulation doping holes in magnetic wells enhances the ferromagnetic ordering temperature above what is achievable in bulk systems. Changing confinement by QW width and depth strongly alters the conduction-band exchange parameter. This is observed in both II–VI and III–V magnetic wells where the kinetic exchange mechanism adds a negative contribution to conduction-band exchange splitting. The use of QW design to engineer spin interactions in magnetic materials could be applied to many materials systems, for example, GaN–AlGaN, in which the effect of magnetic doping in bulk materials has proven difficult to determine. The exchange interactions responsible for ferromagnetic interactions can be probed at low magnetic doping levels since exchange splitting effects are observable at these densities, for example, $10^{19}\,\mathrm{cm^{-3}}$ in GaMnAs QWs. At low doping levels, materials constraints, such as magnetic impurity solubility and associated defect formation can be avoided, which frequently render the origin of ferromagnetism, in some systems, ambiguous and controversial.

1 INTRODUCTION

Spin-dependent electron transport in ferromagnetic metals has been extensively investigated, especially in view of its importance for the functionality of spintronic devices. When electron transport occurs at energies much larger than thermal energies of the order of kT ($kT \sim 26\,\text{meV}$ at 300 K), it is often referred to as '*hot' electron transport*. When hot electrons are transmitted through ferromagnetic metals, they interact with the electrons and atoms in the metal and can be scattered. It is well known that the hot electron mean free paths are spin dependent in ferromagnetic metals. The minority electrons usually have a smaller mean free path than the majority electrons, that is, they are more heavily scattered than the majority electrons. This spin-dependent scattering provides a means of studying the interaction between the hot electron spins and the more localized spins constituting the ferromagnet and also forms the basis for building hot electron spintronic devices.

Various techniques have been developed to study hot electron transport in ferromagnetic metals. These techniques usually require a source of hot electrons with a well-defined energy, a medium in which the electrons travel, and an analyzer for the transmitted electrons. Commonly used electron sources include a semiconductor photocathode, a scanning tunneling microscope (STM) tip, a metal/semiconductor Schottky barrier, and a metal/insulator tunnel barrier. The transmission medium normally contains one or more ferromagnetic-metal layers, separated by nonmagnetic metal or dielectric layers. The electron analyzer may detect both the electron spin's polarization and intensity, such as a Mott detector, or may simply be an energy analyzer, such as a metal/semiconductor Schottky barrier.

Spin-resolved electron transmission is one of the most important techniques for studying hot electron transport in ferromagnetic thin films. Moreover, highly spin-polarized hot electron currents can be obtained after transmission due to the highly efficient spin-filtering effect. Understanding of the spin-filtering effect is key to a variety of applications, including, for example, ballistic electron emission microscopy (BEEM), and the spin-valve transistor and magnetic tunnel transistor devices. The high spin polarization, resulting from spin-filtering, also makes it an attractive approach for hot electron spin injection into semiconductors, which is an important ingredient for the development of useful semiconductor-based spintronic devices.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

2 SPIN-RESOLVED ELECTRON TRANSMISSION

When a hot electron beam impinges on a ferromagnetic surface or interface, the electrons can be reflected, absorbed, or transmitted. Siegmann, Pierce, Celotta (1981) studied electron absorption of a $Ni_{40}Fe_{40}B_{20}$ film for electron energies between 2 and 500 eV. They found that the absorption depends on the orientation of the incident electron spins with respect to the magnetization of the ferromagnetic film. They attributed this dependence to the influence of exchange interactions on elastic spin-dependent electron scattering. They further proposed that the measurement of the absorption current could be utilized for detecting electron spin polarization and probing surface magnetization.

It was later pointed out by Schönhense and Siegmann (1993) that spin-resolved electron transmission through ferromagnetic metals provides a more efficient way of detecting the spin dependence of hot electron transport due to the large asymmetry in the majority and minority electron mean free paths. In typical transmission experiments the ferromagnetic film can only be a few nanometers thick because the transmission efficiency is quite small, $\sim 10^{-3}$ or less, so that the transmitted beam currents lie in the picoampere to nanoampere range, or even less. The first measurement of spin-dependent electron inelastic mean free paths was conducted by Pappas *et al*. (1991) using spin-resolved photoemission. In these experiments, ultrathin Fe overlayers were grown on Cu(100). When photons from the light source impinge on the sample, hot electrons are emitted from the Cu substrate through the Fe overlayer (Figure 1). In order to track the transport of the hot electrons generated in the Cu substrate, energy-resolved spectra were taken so that these electrons could be identified from their element-specific binding energy. The intensity and spin polarization of the hot electrons after transmission through the Fe overlayer was analyzed by a Mott detector. Pappas *et al*. found that the mean free path of the majority electrons is larger than that of the minority electrons in the energy range of $\sim$10–40 eV, and that the mean free paths increase with decreasing electron energy. The rate of increase is larger for the majority electrons than for the minority electrons. Similar experiments were carried out by Getzlaff, Bansmann, and Schönhense (1993) and Vescovo *et al*. (1995) for hcp Co and bcc Fe overlayers on W(110), and fcc Co overlayers on Cu(111), respectively. A spin asymmetry in electron inelastic mean free paths was also observed in these structures.

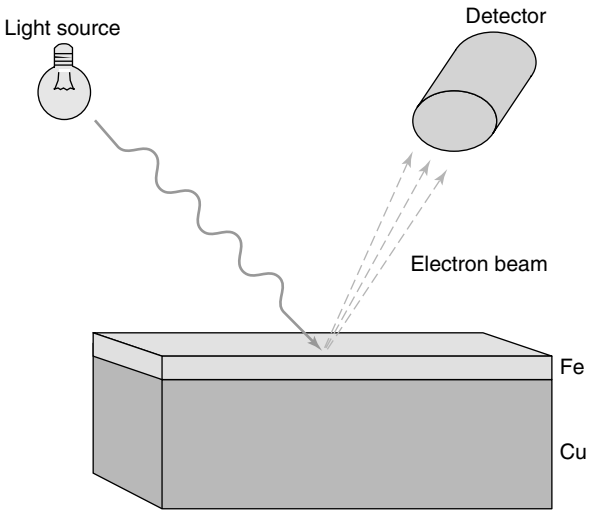

Figure 1. Spin- and energy-resolved photoemission measurements of hot electron transmission through a thin Fe overlayer grown on a Cu substrate.

In the experiments discussed above, the photogenerated electrons are initially unpolarized. They acquire spin polarization while traversing the ferromagnetic overlayer. In a different experiment, Gröbli *et al*. (1995) grew a thin Fe overlayer on a GaAs substrate with a Ag buffer layer between the Fe and GaAs. The Ag layer was used to prevent interdiffusion and reaction between the Fe film and GaAs. Using circularly polarized light (Meier and Zakharchenya, 1984), spin-polarized electrons were created in GaAs and subsequently extracted through the Ag and Fe overlayers. Gröbli *et al*. analyzed the intensity and polarization of the photocurrents as a function of the photon energy and initial electron spin polarization. They found that the transmission was about 1.7 times larger when the electron spin direction was oriented parallel to the Fe magnetization compared to the case when it was antiparallel.

One complication in the overlayer experiments is that the incident light also creates hot electrons inside the overlayer, thereby giving rise to a large background signal. To overcome this problem, self-supporting thin-film structures have been used to study spin-dependent hot electron transmission (Figure 2). The preparation of such structures usually involves deposition of an intermediate layer onto a substrate. Afterwards, the film stack of interest is deposited onto the intermediate layer. Finally, the intermediate layer is removed by dissolving it in a suitable solution, such as water, to obtain freestanding thin films. A GaAs photocathode is often used as the electron source, in which circularly polarized light is used to generate spin-polarized electrons with a polarization vector $\vec{P}$ (Meier and Zakharchenya, 1984). By using self-supporting films, the creation and transmission of hot electrons are no longer intertwined. Consequently, the background signal can be reduced. Lassailly *et al*. (1994) and Drouhin *et al*. (1996) measured hot electron transmission through Au/Co/Au film stacks with the electron spin polarization parallel or antiparallel with the Co magnetization $\vec{M}$. For inelastically scattered electrons, the transmission probability was found to be four

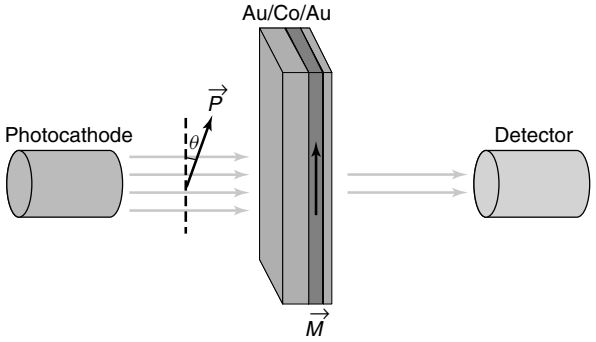

Figure 2. Spin-resolved hot electron transmission measurements through a freestanding ferromagnetic thin-film structure. θ is the angle between the spin polarization of the incident electron beam and the magnetization of the ferromagnet.

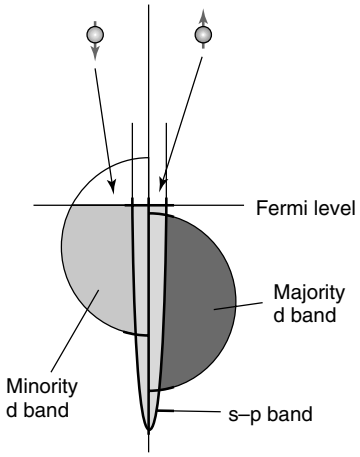

Figure 3. Illustration of spin-dependent electron scattering in 3d transition metals. The horizontal and vertical axes represent the density of states and electron energy, respectively. The filled region represents occupied states. Only the minority electrons (spin-down) can be effectively scattered into the empty minority d band.

times higher for the majority electrons than for the minority electrons. For elastically scattered electrons, the asymmetry in transmission was much smaller, which might be related to the sample preparation (Drouhin *et al*., 1996). Oberli *et al*. (1998) also carried out spin-dependent transmission experiments using a Au/Co/Au film stack. They observed a large transmission asymmetry for elastic electron scattering of up to $\sim$80%.

When the spin polarization vector of the incident electron beam is perpendicular to the magnetization of the ferromagnetic thin film ($\theta = 90^\circ$ in Figure 2), the spin state of the hot electrons can be regarded as a superposition of two components, one parallel and one antiparallel to the film magnetization, with equal amplitude. After the electrons are transmitted through the ferromagnet, the amplitudes of the two components are no longer the same due to spin-dependent absorption. As a result, the spin vector is rotated toward the magnetization direction. Meanwhile, a phase difference between the two components develops and the spin vector precesses around the magnetization. Weber, Riesen, and Siegmann (2001) measured the precession angles of hot electron spins after passing through Fe, Co, and Ni thin films. At an electron energy of 7 eV, they obtained a precession rate of 33, 19, and $7^\circ\,\mathrm{nm}^{-1}$ for Fe, Co, and Ni, respectively. Owing to the conservation of total angular momentum, there must be a corresponding precession of the magnetization of the ferromagnet around the spin vector of the injected hot electrons. It therefore follows that the injection of hot electron spins can be utilized for precessional magnetization reversal (Siegmann *et al*., 1995; Back *et al*., 1998, 1999). Assuming realistic parameters, Weber *et al*. estimated that the switching time using the precession method could be as short as a few picoseconds, which is much faster than conventional magnetic field driven magnetization reversal.

The spin dependence of hot electron scattering in ferromagnetic metals is often considered to be a consequence of electron–electron scattering. In ferromagnetic 3d transition metals the electron d band is split into the majority and minority bands. A portion of the minority electron band is empty, while the majority electron band is almost fully occupied. As a result, minority electron scattering into the empty d band is very effective, giving rise to a shorter mean free path. In contrast, the majority electrons can only be scattered into the less abundant s–p band and thus have a larger mean free path. This simple picture is illustrated in Figure 3. It was found that the inelastic scattering length of hot electrons in transition metals can be described by a simple formula (Schönhense and Siegmann, 1993; Siegmann, 1992), as follows,

$$\frac{1}{\lambda} = \sigma = \sigma_0 + \sigma_d\,(5 - n) \tag{1}$$

where λ and σ are the spin-averaged electron mean free path and scattering cross section, respectively. σ_d accounts for scattering into the empty d bands while σ_0 accounts for other scattering processes. n is the number of occupied d orbitals available to one spin state and since the total number of d orbitals there is 5, $5 - n$ is the number of holes in the d band for one spin state. To account for the different mean free paths of the majority and minority electrons in ferromagnets, Schönhense and Siegmann (1993) extended equation (1) to a spin-dependent format,

$$\frac{1}{\lambda_\pm} = \sigma_\pm = \sigma_0 + \sigma_d\,[5 - (n \pm \Delta n)] \tag{2}$$

where '+' and '−' indicate the corresponding quantities for the majority- and minority-spin electrons, respectively.

$2\Delta n$ is the Bohr magneton number of the ferromagnet. Schönhense and Siegmann obtained good agreement with existing experimental data using equation (2) with a single fitting parameter σ_0/σ_d. They described the spin-dependent hot electron transmission in ferromagnetic transition metals as a spin-filtering effect since the majority electrons are preferentially transmitted while the minority electrons are mostly eliminated after passing through the ferromagnet.

The concept of spin-filtering was successfully used to explain the lack of negative spin polarization observed in photoemission experiments for Co. In strong ferromagnets, such as Co and Ni, the minority d band has a much larger density of states at the Fermi level than the majority d band. Therefore, a negative spin polarization is expected in the photoemission experiments close to the threshold photon energy. This was indeed observed in the case of Ni. For thick Co films, however, the observed polarization is positive at photothreshold (Gröbli *et al*., 1995). This puzzle was understood in light of the spin-filtering effect inside the Co film. Although the light initially excites more minority electrons than majority electrons, they are eliminated from the photocurrent due to their short mean free path. As a result, the majority electrons dominate in the photoemission and a positive spin polarization is observed. If a thin Co film is used with thickness on the order of the minority electron mean free path, a negative spin polarization at photothreshold should be observed since the spin-filtering effect is small for very thin films. Gröbli, Oberli, and Meier (1995) evaporated ultrathin fcc Co overlayers onto Cu(001) and measured the spin polarization of the photocurrent as a function of the Co film thickness. At photo threshold, they obtained a negative spin polarization for film thicknesses up to ∼27 Å. These results provided clear evidence for the spin-filtering effect in ferromagnetic films.

For ultrathin films, the electron mean free path is no longer a well-defined quantity since the motion of the electrons cannot be divided into a succession of single steps. In this sense, spin-dependent electron lifetimes may be a more appropriate quantity to study hot electron transport in ferromagnetic thin films (Aeschlimann *et al*., 1997; Knorren *et al*., 2000). The first direct measurement of spin-dependent electron lifetimes was conducted by Aeschlimann *et al*. (1997) using two-photon photoemission (2PPE) (Figure 4). In the 2PPE experiment, a first laser pulse excites electrons from their ground state into an intermediate state below the vacuum level. After a certain time delay, a second laser pulse excites these electrons above the vacuum level, giving rise to photoemission. The lifetime of the electrons in the intermediate energy state can be extracted by analyzing the intensity and spin polarization of the emitted electrons as a function of the delay time. The energy dependence of the lifetime can be obtained by varying the energy of the laser pulse. Aeschlimann *et al*. measured spin lifetimes in fcc Co films deposited on a Cu(001) single crystal. They found that the electron lifetimes were on the order of a few femtoseconds to 20 fs in the energy range of 0.6–1.1 eV above the Fermi level. The electron lifetime decreased with energy, which was attributed to the increased phase space into which the electrons could be scattered at high energy (Quinn, 1962). The ratio between the majority and minority electron lifetimes was found to be ∼2 at 1 eV and decreased to ∼1.2 at 0.6 eV, which was attributed to the band structure of Co. The density of states of the Co minority electron band has a maximum at ∼1 eV above the Fermi level. When the hot electron energy is less than 1 eV, the number of empty states available for scattering decreases in the minority electron band. On the other hand, the density of states in the majority electron band is more or less constant in this energy range. Therefore, a larger increase in the lifetime of minority electrons than of majority electrons may be expected as the energy is decreased from 1.0 to 0.6 eV.

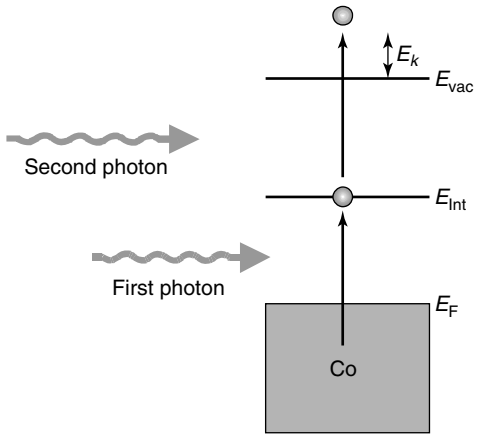

Figure 4. Illustration of the two-photon-photoemission process. E_{Int} and E_{Vac} indicate the energy level of the intermediate state and the vacuum level, respectively. E_k is the kinetic energy of the emitted electrons.

Spin-resolved electron transmission is a powerful technique for investigating spin-dependent hot electron transport in ferromagnetic thin-film structures. Important parameters, such as electron mean free paths and lifetimes, can be extracted from these experiments. These studies provide a solid foundation for developing spintronic devices based on hot electron transport.

3 BALLISTIC ELECTRON EMISSION MICROSCOPY

BEEM was first implemented by Kaiser and Bell (1988). In BEEM, an STM tip is positioned above a metal/semiconductor

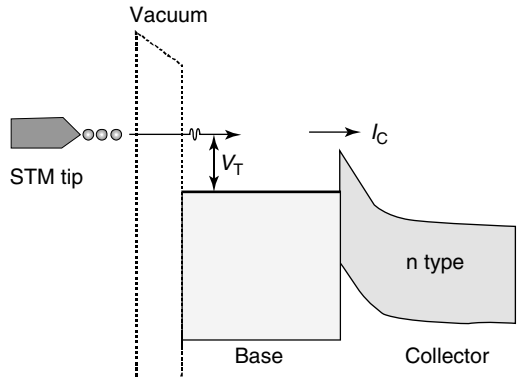

Figure 5. Ballistic electron emission microscopy.

Schottky barrier, where the semiconductor is doped n type (see Figure 5). When a tip bias voltage (V_T) is applied, hot electrons are generated by tunneling from the STM tip into the metal base through the vacuum barrier. If these electrons retain an energy larger than the height of the Schottky barrier (Φ_S) at the metal/semiconductor interface, they can be transmitted into the semiconductor conduction band. The magnitude of the collector current (I_C) is very sensitive to the details of the band structure at the metal/semiconductor interface. Therefore BEEM has been extensively used to probe the electronic structure of buried interfaces (Kaiser and Bell, 1988; Bell and Kaiser, 1988; Schowalter and Lee, 1991; Ludeke and Bauer, 1993; Garcia-Vidal, de Andres and Flores, 1996; Smith and Kogan, 1996; Bell, 1996; Guthrie *et al.*, 1996; Smith, Lee and Narayanamurti, 1998; Weilmeier, Rippard and Buhrman, 1999; Smith *et al.*, 2000). In these studies, the base layer is usually comprised of noble metals, such as Au, which have very large electron mean free paths (Weilmeier, Rippard and Buhrman, 1999).

The hot electrons injected into the metal base have a very high kinetic energy of $\sim E_F + eV_T$. Once they are transmitted into the semiconductor conduction band, their kinetic energy is reduced to $eV_T - \Phi_S$. As a result, the electrons lose a large fraction of their normal momentum component. On the other hand, the transverse momentum component is often assumed to be conserved. This leads to a critical angle of collection (θ_C), and only electrons propagating within this angle may be collected in the semiconductor. θ_C can be calculated using the following formula,

$$\theta_C = \arcsin\sqrt{\frac{m_t}{m}\frac{eV_T - \Phi_S}{E_F + eV_T}} \tag{3}$$

where m_t is the transverse electron effective mass in the semiconductor conduction band and m is the electron mass in the metal base. Assuming typical values of $\frac{m_t}{m} \sim 0.1$, $eV_T -$

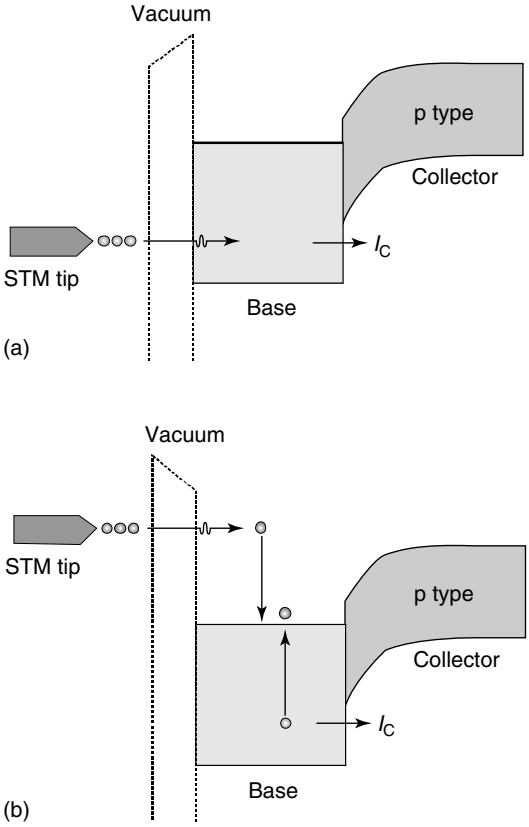

Figure 6. Ballistic hole emission microscopy operating in the normal (a) and reverse (b) modes.

$\Phi_S \sim 0.5\,\text{eV}$, $E_F + eV_T \sim 5\,\text{eV}$, the critical angle is estimated to be less than 6^o. Therefore, the lateral resolution of BEEM can be as high as $\sim$1 nm if the base layer thickness is on the order of 10 nm. The ability to probe subsurface interfaces with such a high resolution is probably the most attractive property of BEEM. Another advantage of BEEM is that the energy of the hot electrons can easily be changed by varying the tip bias voltage, thus allowing for investigations of the energy dependence of hot electron transport over a wide range of energy.

The ballistic transport of hot holes can be studied in a similar manner if the semiconductor collector is doped p type rather than n type (Bell *et al.*, 1990; Hecht *et al.*, 1990). This technique is called *ballistic hole emission microscopy* (BHEM). Figure 6 shows two operation modes of BHEM. When the STM tip is positively biased with respect to the metal base, hot holes are directly injected into the valence band of the collector (Figure 6a). This is the normal operation mode of BHEM. If the STM tip is negatively biased, on the other hand, BHEM operates in the reverse mode (Figure 6b). In this case, hot electrons are first injected into the base, where they are inelastically scattered and lose energy. The energy is transferred to secondary electrons, exciting them to

higher energy states and creating hot holes inside the base layer. Some of these holes then traverse ballistically through the base layer and form the collector current. BHEM has been used to study the transport properties of hot holes, complementary to the study of hot electrons, as well as to probe the electron–hole scattering process in materials.

In order to study the spin dependence of hot electron transport using BEEM, Rippard and Buhrman replaced the noble metal base with single Co films or Co/Cu/Co trilayers (Rippard and Buhrman, 1999, 2000). This variation of BEEM is called *ballistic electron magnetic microscopy* (BEMM). When the hot electrons traverse the Co/Cu/Co base layers, the scattering rate depends on the alignment of magnetization of the two Co layers since the electron mean free paths are spin dependent. As a result, the collector current is maximized when the moments of the two Co layers are parallel and minimized when the moments are antiparallel. By varying the thickness of the Co layers, Rippard and Buhrman extracted spin-dependent electron attenuation lengths of ∼21 and ∼6 Å for the majority and minority electrons in the energy range of 1–2 eV above the Fermi level.

Similar to BEMM, a modification of BHEM allows for the study of the spin dependence of ballistic hole transport in ferromagnetic base layers. This variation is, not surprisingly, referred to as *ballistic hole magnetic microscopy* (BHMM). Banerjee *et al*. (2005) used BHMM to study hot hole transport in Co single layer films and NiFe/Au/Co trilayers grown on a p-type Si collector. For the single layer Co films, they found that the hot hole attenuation length increases from 6 to 10 Å in the energy range from 0.8 to 2 eV at 150 K. For the NiFe/Au/Co base, the transmission of hot holes is clearly spin dependent. The collector current is about 2.3 times larger when the Co and NiFe moments are aligned parallel compared to antiparallel. This corresponds to a large transmission ratio of ∼4.4 for majority and minority holes. Banerjee *et al*. tentatively attributed this spin asymmetry to the difference in group velocities for the majority and minority holes. Further investigation is necessary to determine the origin of the observed spin dependence. BHMM can also operate in the reverse mode. Haq *et al*. (2005) used reverse BHMM to measure hot hole transport in a NiFe/Au/Co spin-valve base. They observed a large collector current change of ∼2.8 times when the alignment of the Co and NiFe moments is switched from antiparallel to parallel.

Another interesting application of BEEM is to study hot electron transport through insulating tunnel barriers, such as Al_2O_3. Tunnel barriers are a key ingredient for spintronic devices such as magnetic tunnel junctions (MTJs) (Julliere, 1975; Miyazaki and Tezuka, 1995; Moodera *et al*., 1995). Understanding the properties of tunnel barriers is therefore crucial for the development of MTJ-based technologies (Parkin *et al*., 1999, 2003). Rippard, Perrella, and Buhrman (2001) fabricated Au/Cu/Co/Al_2O_3/Co/Cu tunnel structures on Si(111), where the Al_2O_3 layer was formed by oxidation of an ultrathin Al film deposited by evaporation or sputtering. They found that evaporated Al formed a uniform tunnel barrier at a much thinner thicknesses (∼6 Å) than sputtered Al. For even thinner films, a significant variation in BEEM current was observed, indicating a nonuniform or discontinuous barrier. The barrier height, on the other hand, was determined to be ∼1.2 eV, independent of the deposition method, barrier thickness, and oxidation conditions. Kurnosikov *et al*. (2002) studied hot electron transport in Ta/Co/Al_2O_3/Ru tunnel junctions without any auxiliary Schottky barriers. A lock-in technique was used in order to extract the small BEEM current from the large background current of the tunnel junction itself. For very thick barriers (∼40 Å), they obtained a barrier height of ∼1.7 eV.

It is worth mentioning that BEEM can be used to probe the luminescence properties of buried structures if a quantum well light-emitting structure is incorporated into the semiconductor collector. This is called *ballistic electron emission luminescence* (BEEL) (Appelbaum *et al*., 2004).

4 SPIN-VALVE TRANSISTOR AND MAGNETIC TUNNEL TRANSISTOR

The use of an STM tip in BEEM as the electron source places a limitation on possible device applications. Monsma *et al*. (1995) introduced a three-terminal solid-state hot electron device–the spin-valve transistor (Figure 7). Similar to BEEM, the spin-valve transistor has a metal base and a semiconductor collector. But instead of an STM tip, a semiconductor emitter is used to create hot electrons by thermionic emission from the emitter Schottky barrier. These electrons subsequently travel across the base layers and are collected by the collector Schottky barrier. To operate the spin-valve transistor, the emitter Schottky barrier height must be

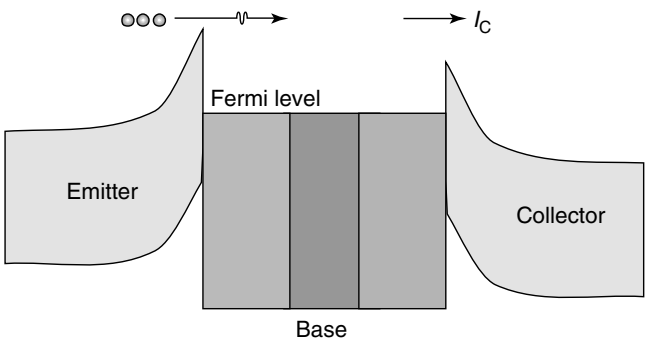

Figure 7. Schematic band diagram of a spin-valve transistor.

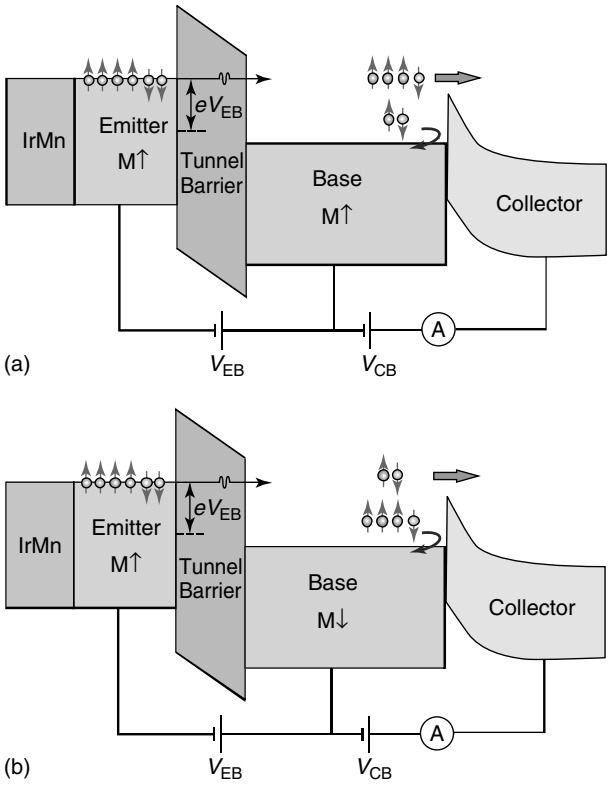

Figure 8. Schematic band diagrams of a magnetic tunnel transistor for a parallel (a) and antiparallel (b) alignment of the emitter and base magnetic moments.

larger than the collector Schottky barrier height. This can be achieved by inserting different metal seed layers at the emitter/base and base/collector interfaces. The base comprises a ferromagnetic-metal/normal-metal/ferromagnetic-metal spin-valve. Thus the magnitude of the collector current can be varied by changing the alignment of the magnetic moments within the spin-valve base. The first room-temperature operation of a spin-valve transistor was realized by Monsma, Vlutters, and Lodder (1998). Spin-dependent hot electron transport in the spin-valve transistor was extensively explored and a very large magnetic field sensitivity was demonstrated at room temperature (Monsma, Vlutters, and Lodder, 1998; Monsma *et al*., (1995); Anil Kumar *et al*., 2000, 2001; Jansen *et al*., 2000, 2001a,b; Vlutters *et al*., 2001, 2002; van 't Erve *et al*., 2002). A detailed review of the spin-valve transistor was given by Jansen (2003).

In the spin-valve transistor, the hot electron energy is determined by the emitter Schottky barrier height. Thus it is not possible to vary the electron energy continuously in one single device. In addition, the difference between the emitter and collector Schottky barrier heights is typically small. Therefore, the collection efficiency of the spin-valve transistor is limited. In order to overcome these problems, a hot electron device called a *magnetic tunnel transistor* was developed (Mizushima *et al*., 1997, 1998; Sato and Mizushima, 2001; van Dijken, Jiang and Parkin, 2002a). One form of the magnetic tunnel transistor consists of a ferromagnetic-metal emitter, a ferromagnetic-metal base, and a semiconductor collector (Figure 8). The emitter and the base are separated by a thin insulating tunnel barrier. A Schottky barrier is formed between the base and the collector with a barrier height Φ_S. Hot electrons are injected from the emitter into the base when an emitter/base bias voltage (V_{EB}) is applied across the tunnel barrier, forming the emitter current (I_E). These electrons traverse the ferromagnetic base layer and are scattered as they do so. The transmitted electrons are subsequently collected in the semiconductor collector but only if their energy remains greater than the Schottky barrier height. Since minority electrons have a short mean free path, they are easily scattered in the base layer. As a result, they lose energy and only a few of them will be collected. In contrast, majority electrons are more likely to maintain their energy due to their large mean free paths. Therefore, more majority electrons will overcome the Schottky barrier and will subsequently be collected. The collector current is very sensitive to the relative alignment of the magnetic moments of the emitter and the base. In the parallel alignment, most of the electrons injected into the base are majority electrons and are scattered less in the base, giving rise to a large collector current (Figure 8a). In the antiparallel alignment, most of the injected electrons are minority electrons and are more heavily scattered, leading to a small collector current (Figure 8b). The switching between the parallel and antiparallel alignment of the magnetic moments can be realized by growing an antiferromagnetic IrMn layer on top of the emitter layer. This IrMn layer is exchange coupled to the emitter and pins the emitter magnetization along a fixed direction. In this case, by applying an appropriate magnetic field, the magnetic moment of the base can be aligned to be either parallel or antiparallel to that of the emitter. The relative change in the collector current when the alignment is switched from antiparallel to parallel can be quantified by the magnetocurrent (MC) parameter, defined as,

$$MC = \frac{I_{C,P} - I_{C,AP}}{I_{C,AP}} \tag{4}$$

where $I_{C,P}$ and $I_{C,AP}$ are the collector current for parallel (P) and antiparallel (AP) alignment of the emitter and base magnetic moments, respectively.

Figure 9(a) shows the collector current as a function of magnetic field at 77 K for a magnetic tunnel transistor with the following structure, GaAs(100)/30-Å $Co_{84}Fe_{16}$/25-Å Al_2O_3/50-Å $Co_{84}Fe_{16}$/300-Å $Ir_{22}Mn_{78}$/50-Å Ta. As the

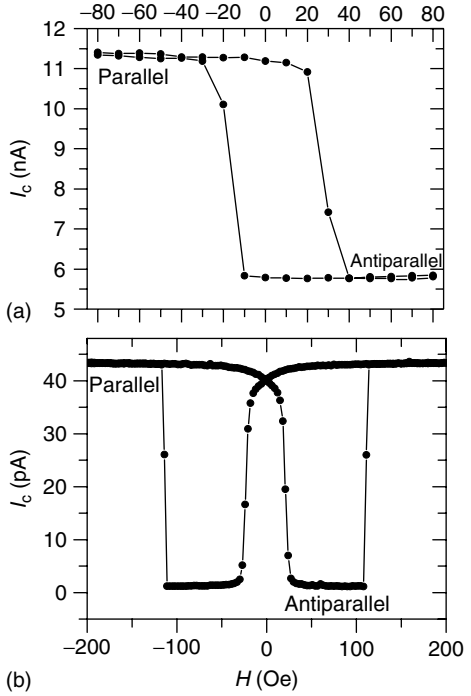

Figure 9. Collector current as a function of the magnetic field for a magnetic tunnel transistor with a single base layer (a) and a spin-valve base (b) at 77 K. The bias voltage is $V_{EB} = 1.0$ V for (a) and 0.8 V for (b).

magnetic field is swept between ± 80 Oe, the base magnetic moment switches at $\sim \pm 20$ Oe, while the emitter magnetic moment remains fixed in the applied field range. At $V_{EB} = 1.0$ V, $I_{C,P}$ ($\sim$11.5 nA) is almost twice as large as $I_{C,AP}$, giving rise to an MC value of 97%.

The moderate MC value in Figure 9(a) is a consequence of the modest tunneling spin polarization of the CoFe/Al_2O_3 emitter, which is typically $\sim$45% (Monsma and Parkin, 2000). Even if spin-filtering in the base is perfect, the maximum MC is of the order of 100%. To enhance the MC effect, a different type of magnetic tunnel transistor was developed using a nonmagnetic metal emitter and a ferromagnetic spin-valve base. In such a device, the initially unpolarized electrons are spin-filtered by the two ferromagnetic layers in the spin-valve base. Much larger MC values can be obtained as spin-filtering can create spin polarization of more than 90% (van Dijken, Jiang and Parkin, 2003a,b). As shown in Figure 9(b), an MC value exceeding 3400% is demonstrated in a magnetic tunnel transistor with the following structure, GaAs(100)/50-Å $Co_{70}Fe_{30}$/40-Å Cu/50-Å $Ni_{81}Fe_{19}$/25-Å Al_2O_3/300-Å Cu. Note that the collector currents shown in Figure 9 are quite small. This is because most of the hot electrons are lost due to scattering in the base and at the base/collector interface. Increasing the hot electron energy can give rise to larger collector currents, up to several microamperes. By optimizing film growth and improving interface properties, the magnitude of the collector current may be further improved (van Dijken, Jiang and Parkin, 2005).

In a simple model ignoring spin-flip processes, the collector current of a magnetic tunnel transistor is carried independently by majority- and minority-spin electrons. The attenuation of hot electron current in each spin channel is described by the corresponding bulk attenuation length and the interface collection efficiency. The collector current for parallel and antiparallel alignments of the emitter and base magnetic moments can be described by the following formula,

$$I_{C,P(AP)} = I_E \frac{1 + P_E}{2} e^{-t/\lambda_{\uparrow(\downarrow)}} \alpha_{C\uparrow(\downarrow)} + I_E \frac{1 - P_E}{2} e^{-t/\lambda_{\downarrow(\uparrow)}} \alpha_{C\downarrow(\uparrow)} \quad (5)$$

where I_E is the tunnel current, P_E is the spin polarization of the electrons injected from the emitter into the base, t is the base layer thickness, $\lambda_{\uparrow(\downarrow)}$ is the attenuation length for the majority (minority) electrons within the ferromagnetic base layer, and $\alpha_{C\uparrow(\downarrow)}$ is the electron collection efficiency at the base/collector interface.

van Dijken, Jiang, and Parkin (2002b) fabricated a series of magnetic tunnel transistors with different CoFe base layer thicknesses and measured the thickness dependence of the collector current for parallel and antiparallel alignments at various emitter/base bias voltages V_{EB} (i.e., hot electron energy). By fitting the data to equation (5), they obtained hot electron attenuation lengths in the energy range of 1–1.9 eV. As shown in Figure 10, the attenuation length of majority electrons is about 5–6 times larger than that of the minority electrons. Moreover, the attenuation length of majority electrons decreases with electron energy, whereas the attenuation length of minority electrons hardly shows any energy dependence. The difference in scattering cross sections for the majority and minority electrons $\Delta\sigma = \sigma_\downarrow - \sigma_\uparrow = 1/\lambda_\uparrow - 1/\lambda_\downarrow$ can be calculated using the attenuation lengths. This result is plotted in the inset of Figure 10 together with some data obtained by Oberli *et al.* for Co thin films at electron energies of $\sim$5–16 eV (Oberli *et al.*, 1998).

The decrease of the attenuation length of majority electrons at elevated energies is due mainly to an enhanced electron–electron scattering rate, which is the most important scattering mechanism for majority electrons (Quinn, 1962; Zarate, Apell and Echenique, 1999; Drouhin, 2001). On the other hand, the minority electrons are subject to more efficient scattering because of the abundant availability of empty minority d band states near the Fermi level and additional scattering mechanisms such as spontaneous spin-wave scattering (Vlutters *et al.*, 2002). As a result, the

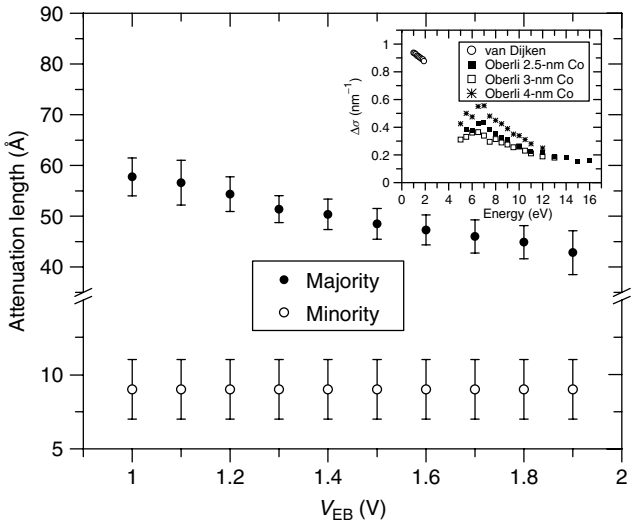

Figure 10. Majority and minority electron attenuation lengths in CoFe thin films as a function of the electron energy (van Dijken, Jiang and Parkin, 2002b). The inset shows the difference in scattering cross sections for majority and minority electrons at electron energy of ∼1–16 eV (Oberli *et al*., 1998; van Dijken, Jiang and Parkin, 2002b).

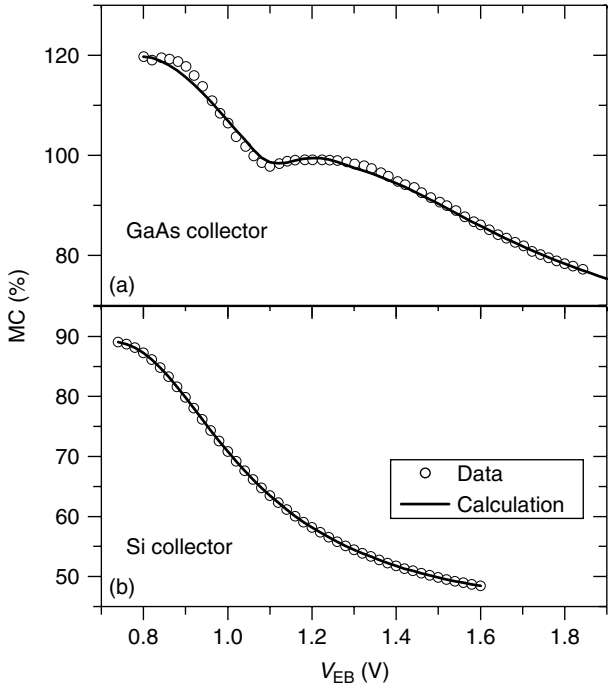

Figure 11. Bias dependence of the MC in magnetic tunnel transistors with a GaAs (a) and Si (b) collector (van Dijken, Jiang and Parkin, 2003c; Jiang *et al*., 2004). The symbols and lines indicate experimental data and model calculation results, respectively.

minority electron attenuation length is much smaller. The large spin asymmetry in the attenuation lengths implies that the hot electron current in the magnetic tunnel transistor, after spin-filtering in the base region, can be highly spin-polarized (van Dijken, Jiang and Parkin, 2002b). Using the attenuation lengths plotted in Figure 10, the spin polarization of the hot electron current at the base/collector interface is more than 95% when the CoFe base layer thickness exceeds ∼35 Å.

The collector current in a magnetic tunnel transistor is determined not only by the electron transmission in the ferromagnetic base layer, but also by the conduction band structure of the semiconductor collector. For example, the bias dependence of the MC is very different for magnetic tunnel transistors with GaAs and Si collectors. This is illustrated in Figure 11, where the MC is measured as a function of V_{EB} for two magnetic tunnel transistors with GaAs and Si collectors (van Dijken, Jiang and Parkin, 2003c; Jiang *et al*., 2004). In the case of a GaAs collector, a pronounced nonmonotonic bias dependence of the MC is observed (Figure 11a). When the bias voltage V_{EB} exceeds the Schottky barrier height (∼0.78 V), a large MC is obtained. The MC decreases with V_{EB} up to ∼1.1 V, then increases slightly, and finally decreases gradually. In contrast, for the magnetic tunnel transistor with a Si collector, the MC decreases continuously as a function of the bias voltage (Figure 11b).

In the magnetic tunnel transistor, the spin-polarized hot electrons that are injected from the emitter into the base initially have very narrow energy distribution because the tunneling process is highly sensitive to the height of the tunnel barrier. Specifically, the electrons are injected with energies close to the emitter Fermi level. As these electrons traverse the base region, they experience inelastic scattering and lose energy. As a consequence, the energy distribution of the hot electrons broadens. Since the scattering rate is normally higher for the minority electrons than for the majority electrons, the minority electrons are more likely to lose energy and thus have a broader energy distribution. Additional electron scattering occurs at the base/collector interface, after which a fraction of the incident electrons are collected by the semiconductor. This interface scattering likely broadens the angular distribution of the hot electrons.

The GaAs conduction band has an energy minimum at the center of the Brillouin zone (Γ valley). At an energy of ∼0.29 eV above the top of the Schottky barrier, there are eight local minima along the ⟨111⟩ axis (L valleys). At even higher energy, ∼0.48 eV above the Schottky barrier height, there are six local minima along the ⟨001⟩ axis (X valleys) (Blakemore, 1982). When the bias voltage exceeds the Schottky barrier height by a small margin, a hot electron current is collected through the central Γ valley. Because of their narrow energy distribution, a relatively large portion of the majority electrons is able to surmount the Schottky barrier and hence contributes to the collector current. On the

other hand, only a small portion of the minority electrons has enough energy to be collected. This large spin asymmetry results in a large MC. At elevated emitter/base bias voltages, increasingly more of the scattered minority electrons are able to surmount the Schottky barrier. The increase of the minority electron current gives rise to a smaller MC. If all the collector conduction bands open up at the same energy level, a monotonic decrease of the MC with bias is expected, as observed in the magnetic tunnel transistor with a Si collector. However, for GaAs, the L and the X valleys open up at higher energies than the Γ valley. When these valleys just become available for hot electron injection, they favor the collection of the majority electrons and thus tend to increase the MC. This leads to the observed nonmonotonic bias dependence of the MC when the collector is GaAs. An implication in this argument is that the hot electrons at the base/collector interface have a broad angular distribution, thus allowing them to access the L valleys in GaAs with large transverse momentum components. This can be justified by strong electron scattering at the base/collector interface (Smith, Lee and Narayanamurti, 1998; van Dijken, Jiang and Parkin, 2002b, 2003; Jiang *et al*., 2004). The calculated results based on this model are shown as lines in Figure 11. An excellent agreement is obtained between the experiments and calculations.

5 HOT ELECTRON SPIN INJECTION

The development of modern-day electronics has followed Moore's law for several decades, in which the channel length of a silicon MOSFET is halved about every 18–24 months, allowing for a doubling of the number of transistors (Moore, 1965). However, as the transistor size continues to shrink towards fundamental physical limits, there is an increasing interest in exploring alternate technologies to both silicon and purely charged based devices. Spintronics is a particularly promising technology, where the spin states of carriers are utilized as an additional degree of freedom for improved information processing and data storage (Zutic, Fabian and Sarma, 2004). The electron's spin has already played an important role in magnetoelectronic devices, such as the spin valve and the magnetic tunnel junction. The discovery of the giant magnetoresistance and the tunneling magnetoresistance effects has had a profound impact on the magnetic recording industry (Julliere, 1975; Miyazaki and Tezuka, 1995; Moodera *et al*., 1995; Parkin *et al*., 1999, 2003; Baibich *et al*., 1988; Binasch *et al*., 1989; Parkin, More and Roche, 1990; Parkin, Bhadra and Roche, 1991). In semiconductor electronics, however, the role of spins is rather passive. It is interesting to note that semiconductors have many desirable properties as far as spins are concerned. In particular, the electron

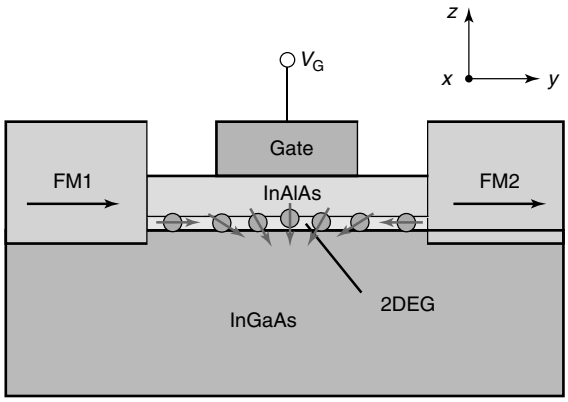

Figure 12. Schematic drawing of the Datta–Das transistor. FM1 and FM2 are two ferromagnetic contacts to the 2DEG.

spin relaxation time in semiconductors can be several orders of magnitude longer than the electron momentum and energy relaxation times (Kikkawa and Awschalom, 1998). Using an electric field, electrons in GaAs can be dragged over a distance of 100 μm without losing their spin coherence (Kikkawa and Awschalom, 1999). In addition to the long spin lifetimes and large spin diffusion lengths, semiconductors offer the flexibility of electrically controlled variable carrier doping densities and profiles and spin relaxation rates, which could be useful for building interesting spintronic devices. For example, Ohno *et al*. (2000) showed that it is possible to control the ferromagnetism of InMnAs thin films by modulating the hole concentration. Sandhu *et al*. (2001) and Karimov *et al*. (2003) demonstrated that the electron spin relaxation rates in GaAs heterostructures can be varied by applying a gate voltage. Murakami *et al*. predicted that a dissipationless spin current flows in GaAs in the presence of an electric field (Murakami, Nagaosa and Zhang, 2003). These studies suggest that spin-based semiconductor electronics has the potential to develop an entirely new generation of devices with high speed, high density, low power consumption, and nonvolatility (Wolf *et al*., 2001).

One of the first semiconductor spintronic devices was proposed by Datta and Das (1990) (Figure 12) and is often referred to as the Datta–Das 'transistor'. This device is comprised of two ferromagnetic contacts placed on top of a semiconductor two-dimensional electron gas (2DEG) formed at an InAlAs/InGaAs interface. The two ferromagnetic contacts serve as the injector and detector of spin-polarized electrons, respectively. The 2DEG forms a channel for electron transport between the contacts. Owing to the Rashba effect (Rashba, 1960; Bychkov and Rashba, 1984), the mobile electrons in the 2DEG sense an effective magnetic field and precess around this field. The strength of the magnetic field can be controlled by applying a gate voltage across the 2DEG (Nitta *et al*., 1997). Therefore, it is possible to modulate the

electron spin precession inside the 2DEG and, consequently, the magnitude of the current. Although simple in concept, the Datta–Das transistor contains all the essential components of a semiconductor spintronic device, the creation, transport, manipulation, and detection of spin-polarized electrons, by electrical means. The first step, the creation of spin-polarized electrons inside semiconductors, can be realized by electrical spin injection. It is a prerequisite for semiconductor spintronics.

It has long been known that spin-polarized electrons can be generated in direct band gap semiconductors by optical pumping with circularly polarized light (Meier and Zakharchenya, 1984). For device applications, however, electrical means of spin injection is more desirable. The first attempts at electrical spin injection were carried out using Ohmic contacts formed by ferromagnetic metals (Monzon and Roukes, 1999; Gardelis *et al*., 1999; Filip *et al*., 2000). Since the electrons in the ferromagnetic metals are spin-polarized, it was expected that the electrons injected into the semiconductors would maintain their spin orientation and thus give rise to successful spin injection. Despite significant effort, however, unambiguous spin injection was not demonstrated. Later on, it was realized that the conductivity mismatch between the metal and the semiconductor might present a fundamental obstacle to spin injection (Schmidt *et al*., 2000). The conductivity mismatch can be understood in a simple picture, as shown in Figure 13. In the spin injection experiment, the resistance of the device can be divided into a spin-independent part $R_0^{\uparrow} = R_0^{\downarrow}$ and a spin-dependent part $R_S^{\uparrow} \neq R_S^{\downarrow}$, where the up (down) arrow represents the majority (minority) electron channel. The semiconductor resistance is normally spin independent, whilst the ferromagnet/semiconductor contact resistance is spin dependent. When an Ohmic contact is used, $R_S^{\uparrow,\downarrow}$ is much smaller than $R_0^{\uparrow,\downarrow}$. Therefore, the electron transport is dominated by the spin-independent semiconductor resistance. As a result, the electron current is not polarized. In order to achieve efficient spin injection, the spin-dependent conductivity needs to be smaller than its spin-independent counterpart. Note that Figure 13 is a rather simplistic picture of the conductivity mismatch problem. A more detailed treatment of this subject was given by Schmidt *et al*. (2000).

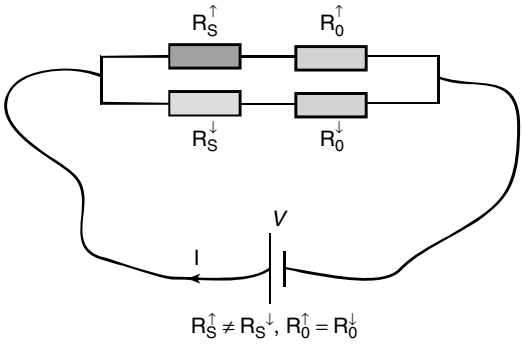

Figure 13. A simplistic picture to illustrate the conductivity mismatch problem in spin injection experiments.

The first evidence of electrical spin injection was reported by Hammar *et al*. (1999). They used NiFe contacts to inject electrons into an InAs 2DEG, with a thick AlGaSb insulating barrier inserted between the NiFe and the 2DEG. Owing to the Rashba effect, the spin degeneracy of the electron density of states in the 2DEG is lifted. As a result, electron transport in the 2DEG channel is spin dependent. When the magnetization of the NiFe contacts is varied by a magnetic field, the resistance of the device is expected to change (Johnson, 1998). Indeed, Hammar *et al*. observed a resistance change of $\sim$0.9%. This observation, although a small effect, was an encouraging step towards spin injection. Hu *et al*. (2001) also reported spin injection from NiFe into an InAs 2DEG, with a smaller resistance change of $\sim$0.2%.

Much larger spin injection effects were obtained using diluted magnetic semiconductors whose conductivity matches that of normal semiconductors. The use of magnetic semiconductors was proposed by Oestreich *et al*. (1999). Using time-resolved photoluminescence, they showed that the magnetic semiconductor $Cd_{0.98}Mn_{0.02}Te$ could serve as a very good spin aligner in a magnetic field of 2.5 T. Moreover, the spin-polarized electrons generated in the $Cd_{0.98}Mn_{0.02}Te$ layer could be efficiently transported into an adjacent CdTe layer. Shortly afterwards, Fiederling *et al*. (1999), Ohno *et al*. (1999), and Jonker *et al*. (2000) demonstrated electrical spin injection using BeMnZnSe, GaMnAs, and ZnMnSe spin injectors, respectively. In these experiments, a quantum well light emitting diode (LED) was used as an optical detector to measure the spin polarization of the injected electrons (Figure 14). The injected electrons recombine with

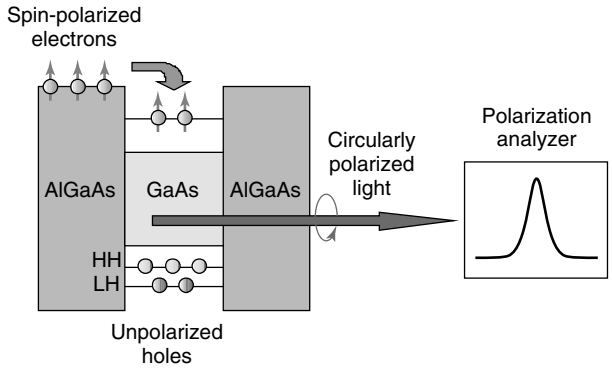

Figure 14. Schematic drawing of a quantum well LED detector used for measuring the spin polarization of injected electrons. HH and LH represent the heavy and light holes in the quantum well, respectively.

holes inside the quantum well and emit light. The degree of circular polarization of the emitted light is correlated to the spin polarization of the electrons prior to recombination through optical selection rules (Meier and Zakharchenya, 1984). Therefore, the spin polarization can be inferred from the luminescence polarization. Very large spin polarizations of more than 80% were reported for magnetic semiconductor injectors (Jonker *et al*., 2001). Such a high spin polarization is very desirable for spintronic applications. However, magnetic semiconductors have limitations. These materials, to date, only possess the desired magnetic properties at temperatures well below room temperature and/or in a large magnetic field, thereby limiting their usefulness.

Ferromagnetic 3d transition metals have Curie temperatures much higher than room temperature, making them attractive for spin injection into semiconductors. However, care must be taken to overcome the conductivity mismatch between the metal and the semiconductor. Rashba pointed out that the mismatch problem can be resolved if the ferromagnetic metal forms a tunnel contact with the semiconductor since the tunneling process is spin dependent and tunnel contacts can have a high impedance (Rashba, 2000). This predication was confirmed by Zhu *et al*. (2001). Using a Fe/GaAs Schottky tunnel contact, they observed a spin polarization of ∼2% in GaAs/InGaAs quantum wells. Following the same route, higher spin polarizations were reported by the Jonker group at the Naval Research Laboratory (Hanbicki *et al*., 2002, 2003) and the Crowell and Palmstrøm groups at the University of Minnesota (Adelmann *et al*., 2005), reaching ∼30% at low temperatures. Crooker *et al*. used a magneto-optical Kerr technique to directly image electrical spin injection and accumulation in a lateral GaAs device with Fe Schottky contacts (Crooker *et al*., 2005). Electrical detection of spin injection and accumulation was recently demonstrated by Lou *et al*. (2006, 2007) who show that the nonequilibrium spin population in the semiconductor gives rise to a measurable voltage signal. Moreover, they show that the suppression of the voltage signal by a small transverse magnetic field is consistent with spin precession and dephasing induced by the magnetic field.

Besides Schottky tunnel contacts, oxide tunnel barriers were also utilized for spin injection. Manago and Akinaga utilized ferromagnetic metals in conjunction with Al_2O_3 tunnel barriers as the spin injector and observed a signal of ∼1% at room temperature (Manago and Akinaga, 2002). van 't Erve *et al*. (2004) fabricated Fe/Al_2O_3 tunnel injectors and measured a spin polarization of 40% at 5 K. Motsnyi *et al*. (2002, 2003) and Van Dorpe *et al*. (2003) used the oblique Hanle effect (Meier and Zakharchenya, 1984) to investigate spin injection from a ferromagnetic-metal/Al_2O_3-tunnel-barrier injector into a GaAs LED. They applied a magnetic field at an angle to the ferromagnetic-metal film plane and measured the circular polarization of the light emitted from the LED. Motsnyi *et al*. (2003) obtained a light polarization of ∼4% at 80 K and ∼1% at room temperature. By model fitting, they concluded that the actual spin injection efficiency is about 21 and 16%, respectively.

When a Schottky or Al_2O_3 tunnel contact is used for spin injection, the maximum spin polarization that can be achieved may be limited by the tunneling spin polarization of the ferromagnetic metal. For instance, for 3d ferromagnetic metals and their alloys, the tunneling spin polarization is normally no more than 50% when an Al_2O_3 tunnel barrier is used (Monsma and Parkin, 2000). To overcome this limit, two approaches can be adopted for spin injection of highly spin-polarized electrons. One is to take advantage of the spin-filtering effect of hot electrons in ferromagnetic metals to obtain high spin polarization. The other is to develop new materials which give rise to high tunneling spin polarization. These two approaches will be discussed below.

In the previous section, it has been shown that the spin polarization of the hot electron current in a magnetic tunnel transistor can be as high as 95% at the base/collector interface due to efficient spin-filtering in the base. Moreover, the presence of a tunnel barrier in the magnetic tunnel transistor solves the conductivity mismatch problem. Because of these properties the magnetic tunnel transistor holds promise as a highly efficient spin injector. To detect the injected electron spin polarization, a quantum well LED structure is incorporated into the collector of the magnetic tunnel transistor. In this scheme, the injected electrons recombine with unpolarized holes from the substrate in the quantum well and emit light. By analyzing the circular polarization of the light, the spin polarization of the electrons can be determined using the optical selection rules (Meier and Zakharchenya, 1984). As shown in Figure 15, there are two types of holes in the quantum well, the heavy holes (HHs) and the light holes (LHs). They both can recombine with the electrons and emit photons with opposite helicity. In general, careful analysis of these data must be made in order to properly extract the electron's spin polarization from the luminescence spectra. However, in the quantum well, the energy degeneracy of the heavy and light hole states is lifted due to confinement and/or strain effects. If the energy splitting between the two hole states (ΔE) is larger than the spectral resolution, it is possible to measure the circular polarization of the HH emission only. In this case, the luminescence polarization is simply equal to the electron spin polarization. Note that the selection rules in Figure 15 are only valid in the Faraday geometry, that is, with the spin

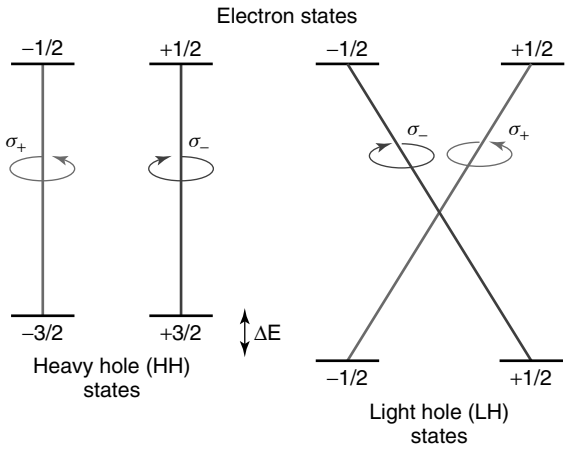

Figure 15. Optical selection rules for electron–hole recombination in the Faraday geometry.

and light propagation directions both perpendicular to the quantum well plane. Experimentally, this requires the use of a large magnetic field to rotate the electron spin moment out of the film plane.

In the spin injection experiment, the quantum well detector is buried inside the semiconductor heterostructure. The injected electrons are first transported into the quantum well region, where they spend a certain amount of time (described by the recombination time) before recombining with the holes and emitting light. The measured electroluminescence (EL) polarization does not take into account any spin relaxation effects prior to recombination and, therefore, sets a lower bound on the spin polarization of the injected electrons. To properly interpret the experimental data, it is necessary to take into account various spin relaxation processes in the semiconductor. Three spin relaxation mechanisms are known to be particularly important, the Elliott–Yafet (EY), D'yakonov–Perel' (DP), and Bir–Aronov–Pikus (BAP) mechanisms. The EY process derives from the mixing of electron wave functions of opposite spin states due to spin-orbit coupling (Elliott, 1954; Yafet, 1963). As a result, electron momentum scattering leads to spin relaxation, with a rate proportional to the momentum scattering rate. The DP process is present in semiconductors without inversion symmetry (D'yakonov and Perel', 1971; D'yakonov and Kachorovskii, 1986). The mobile electrons see an effective magnetic field whose magnitude and orientation depend on the electron momentum. Spin precession around this magnetic field gives rise to spin relaxation. Momentum scattering randomizes the direction of the effective magnetic field and reduces the average precession effect. The DP spin relaxation rate is therefore inversely proportional to the momentum scattering rate, which is opposite to the EY process. The BAP process is due to electron–hole exchange and annihilation interactions (Bir, Aronov and Pikus, 1976). The relative importance of the three processes depends on the details of the sample structure and the experimental conditions, such as the semiconductor doping profile, experiment temperature, and so on.

Jiang *et al*. (2003) conducted spin injection experiments at 1.4 K using a magnetic tunnel transistor as the spin injector. The emitter of the magnetic tunnel transistor was made up of 50-Å CoFe. The base consisted of 35-Å NiFe and 15-Å CoFe with the NiFe layer adjacent to the collector. The tunnel barrier was Al_2O_3 with a thickness of ∼22 Å. Three GaAs/$In_{0.2}Ga_{0.8}$As quantum wells were incorporated in the collector as the optical detector. Figure 16 shows the EL spectra at a hot electron energy of ∼2 eV, where the thin and thick lines represent the left ($\sigma+$) and right ($\sigma-$) hand circular polarization components, respectively. Note that the width of the luminescence peaks is only ∼25 Å, which is limited by the spectrometer resolution for the given signal level. According to absorption studies, the separation in wavelengths between the HH and LH emissions is ∼400 Å in these GaAs/$In_{0.2}Ga_{0.8}$As quantum wells. Therefore, the narrow luminescence linewidth enables the unambiguous detection of recombination between electrons and HHs. As mentioned before, in this case the circular polarization of the EL is equal to the spin polarization of the electrons just before recombination.

The EL in Figure 16 clearly depends on the magnetic field. At zero field, the intensities of the $\sigma+$ (I^+) and $\sigma-$ (I^-) components are equal. At high fields, there is a significant difference between I^+ and I^-. Here, the intensities are calculated by integrating the areas under the peaks. The EL polarization is defined as,

$$P_{\mathrm{EL}} = \frac{I^+ - I^-}{I^+ + I^-} \tag{6}$$

P_{EL} is ∼13% at 2.5 T and ∼ − 13% at −2.5 T. The sign of P_{EL} indicates injection of majority electron spins into the quantum wells. This result is consistent with the sign of the collector current polarization observed in electrical transport measurements in magnetic tunnel transistors. Excitons in $In_{0.2}Ga_{0.8}$As have a large g factor, leading to a large Zeeman splitting energy in the quantum wells, which is shown by the shift of the EL peak center positions for $\sigma+$ and $\sigma-$ components at high fields.

The relatively small collector current of the magnetic tunnel transistor requires the device to operate at high electron energy in order to obtain enough signal in the spin injection experiments. Electron spin relaxation, however, is very efficient at high energy (Meier and Zakharchenya, 1984; Krishnamurthy, van Schilfgaarde and Newman, 2003), leading to a moderate EL polarization of the order of ∼10%. To

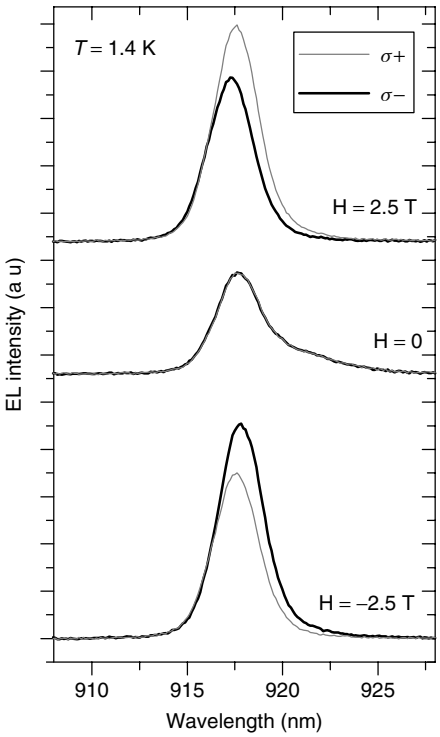

Figure 16. Electroluminescence spectra measured in magnetic fields of 0 and ±2.5 T at 1.4 K for a magnetic tunnel transistor spin injector. The thin and thick lines represent the $\sigma+$ and $\sigma-$ circular polarization components, respectively. (Jiang *et al*., 2003.)

increase the electron current at lower energy while maintaining a high spin polarization, crystalline CoFe/MgO tunnel injectors have been used. The tunneling spin polarization of a CoFe/MgO(100) structure was predicted to be very high using first principle calculation (Butler *et al*., 2001; Mathon and Umerski, 2001; Zhang and Butler, 2004). Experimentally, tunneling spin polarization as high as 85% was reported by Parkin *et al*. (2004). Therefore, a CoFe/MgO tunnel injector is capable of injecting highly spin-polarized electrons into semiconductors.

Successful spin injection using a CoFe/MgO tunnel injector was demonstrated for the first time by Jiang *et al*. (2005). In their experiment, the injector consists of 50-Å $Co_{70}Fe_{30}$ and 30-Å MgO capped with 100-Å Ta, and the detector contains a GaAs/AlGaAs quantum well light-emitting diode. A large electroluminescence polarization of ∼47% was observed at room temperature in a magnetic field of 5 T, as shown in Figure 17. A nonmonotonic temperature dependence of the EL polarization was observed, which was related to the temperature dependence of spin relaxation rate and electron recombination time in the quantum well detector. In spin injection experiments, the measured luminescence polarization P in a steady state is given by (Meier and

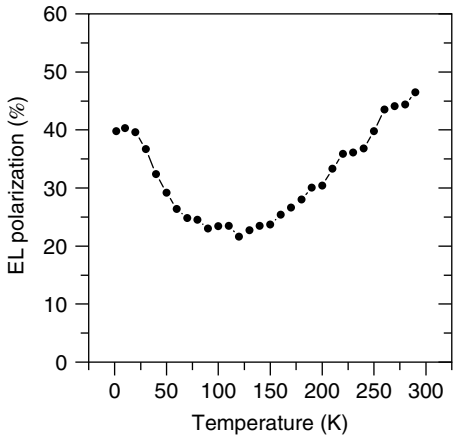

Figure 17. Temperature dependence of the electroluminescence polarization at 5 T for a CoFe/MgO tunnel spin injector (Jiang *et al*., 2005).

Zakharchenya, 1984),

$$P = \frac{\tau_S}{\tau_S + \tau_R} P_0 \tag{7}$$

where P_0 is the initial spin polarization of the electrons injected into the quantum well, τ_S and τ_R are the spin and electron lifetimes, respectively. Both τ_S and τ_R vary with temperature and contribute to the temperature dependence of the luminescence polarization (Meier and Zakharchenya, 1984; Krishnamurthy, van Schilfgaarde and Newman, 2003; Ohno *et al*., 1999; Malinowski *et al*., 2000; Lau, Olesberg and Flatté, 2001; Puller *et al*., 2003; Feldmann *et al*., 1987; Gurioli *et al*., 1991; Tignon *et al*., 1998; Fernández-Alonso *et al*., 2003). Salis *et al*. (2005) measured τ_S and τ_R in GaAs/AlGaAs quantum well detectors using a spin-resolved Kerr technique. They found that the observed dip in the luminescence polarization was largely due to a maximum electron lifetime at intermediate temperatures. On the basis of these measurements, Salis *et al*. suggested that the initial spin polarization of the injected electrons was ∼70%, independent of temperature.

The observation of efficient spin injection at room temperature using a CoFe/MgO tunnel injector is consistent with the high Curie temperature of CoFe and the weak temperature dependence of spin-dependent tunneling. The actual spin injection efficiency is higher than that inferred from the polarization of the quantum well EL because of spin relaxation in the quantum well detector. The MgO-based spin injector can readily be fabricated by sputter deposition. In addition, the MgO barrier prevents intermixing of the ferromagnetic metal and the semiconductor, leading to improved thermal stability (Wang *et al*., 2005). These desirable features make MgO-based tunnel spin injectors attractive for future semiconductor spintronic applications.

6 CONCLUSION

A great deal of progress has been made in the field of hot electron spintronic physics over the decade. These materials and devices are particularly interesting for the study of the physics of the spin-dependent scattering properties of electrons with energies just above the Fermi energy, an energy range which is difficult to access by other techniques. Moreover, spin-based hot electron devices have promise for semiconductor-based spintronic devices, particularly for the purpose of the injection of highly spin-polarized current into semiconductors.

Spin-dependent Transport of Carriers in Semiconductors

Roland Winkler

Northern Illinois University, DeKalb, IL, USA and Argonne National Laboratory, Argonne, IL, USA

1 INTRODUCTION

Broadly speaking, spin-dependent transport phenomena in semiconductors can be divided into two categories. On the one hand, we have those effects such as spin drift, spin diffusion, and spin precession that refer to the transport of spin-polarized carriers. These effects are of central importance for spintronics device concepts where the generation of spin-polarized distributions of carriers are spatially separated from those elements that manipulate and detect the spins. On the other hand, we also have spin-dependent phenomena such as the spin Coulomb blockade or weak localization and spin-split Shubnikov–de Haas oscillations visible in magneto-transport of two-dimensional (2D) electron systems. The latter effects provide important insights into the nature of the spin-dependent interactions, such as exchange and spin-orbit coupling, that can be exploited for the manipulation of spin systems. In this review, we will focus mostly on the former class of phenomena. Also, we will focus mostly on homogenous systems and touch only briefly on the properties of structured devices that are discussed in **Semiconductor Spintronic Devices, Volume 5**.

We begin with a discussion of optical orientation of electron spins in semiconductors (Section 2). Then we review nonequilibrium spin flow including spin drift and diffusion (Section 3.1), and spin precession (Section 3.2). Coulomb effects in spin transport are discussed in Section 3.3. Finally, we review in Section 4 spin photocurrents and the reverse effect, the electrical generation of a spin polarization.

2 OPTICAL ORIENTATION OF ELECTRON SPINS

Various schemes have been developed to generate spin-polarized carrier distributions in nonmagnetic semiconductors. Broadly speaking, these fall into three categories. First, optical excitation allows creation of spin-polarized electrons inside the semiconductor. Second, magnetic layers can be used to inject spin-polarized carriers into the semiconductors. These magnetic layers can be semimagnetic semiconductors (see also **Diluted Ferromagnetic Semiconductors – Theoretical Aspects, Volume 5**), ferromagnetic semiconductors (see also **Ferromagnetic Semiconductors, Volume 5**) or ferromagnetic metal electrodes attached to the semiconductor (Jonker, 2003). Finally, dynamic phenomena based on electric fields and charge currents can give rise to

spin polarization inside the semiconductor or spin accumulation at the edges of the sample (see Section 4.2 and **Theory of Spin Hall Effects in Semiconductors, Volume 5**).

Here, we will focus on the *optical orientation* of electrons that has proven to be a powerful technique since some of the earliest studies of spin-related phenomena in semiconductors were performed (Lampel, 1968; Meier and Zakharchenya, 1984). In direct semiconductors like GaAs, the electron states in the conduction band have spin $S = 1/2$, whereas the hole states in the valence band have an effective spin $S = 3/2$. The hole states with spin z component $S_z = \pm 3/2$ are denoted heavy-hole (HH) states, whereas the light-hole (LH) states have $S_z = \pm 1/2$. Left (right) circularly polarized photons carry a z component of angular momentum of -1 $(+1)$ so that conservation of angular momentum results in the selection rules for optical transitions depicted in Figure 1. A more detailed analysis shows that the probabilities for transitions from the HH states to the conduction band are three times larger than the probability for optical transitions from the LH states. In bulk semiconductors, the maximum attainable degree of spin polarization is thus $P = 50\%$, where P is defined as

$$P = \frac{N_+ - N_-}{N_+ + N_+} \tag{1}$$

and N_+ (N_-) is the number of electrons with spin up (down), respectively. In 2D systems, the degeneracy of the HH and LH states is lifted as sketched in Figure 1. For resonant excitation at the HH energy we thus expect a rise of the maximum attainable degree of polarization up to $P = 100\%$.

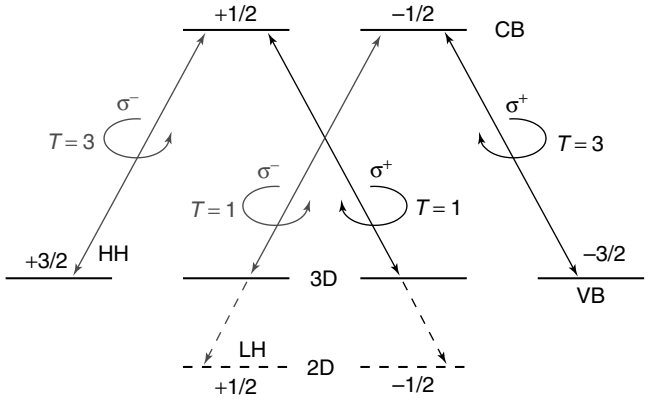

Figure 1. Selection rules and relative transition rates T for optical transitions between valence band (VB) states having an effective spin $S = 3/2$ and conduction band (CB) states with $S = 1/2$ (Dyakonov and Perel, 1984)). In bulk semiconductors, the HH states ($S_z = \pm 3/2$) are degenerate with the LH states ($S_z = \pm 1/2$) whereas in quasi-2D systems the LH states (dashed bold lines) are lower in energy than the HH states.

A particular advantage of the optical orientation scheme lies in the fact that it holds both for absorption and emission, so that it can be used for creating and for detecting spin-polarized carrier distributions. However, the holes lose their spin orientation significantly faster than the electrons, and the oriented electrons can recombine with *any* hole. Therefore, Figure 1 implies that the polarization of the recombination photoluminescence (PL) in bulk semiconductors does not exceed ∼25%. (This does not apply to 2D systems where the recombination PL is due to a transition from the lowest electron to the lowest HH state.)

Even in a single-particle picture for the optical excitation, the 3 : 1 ratio of HH and LH transitions is obtained only if HH–LH coupling of the hole states at nonzero wave vectors $\mathbf{k}$ is neglected. Owing to this HH–LH coupling, the hole states with $k > 0$ are not spin eigenstates. Furthermore, a realistic picture must take into account that optical absorption gives rise to the formation of excitons, that is, Coulomb correlated electron-hole pairs. Thus even for excitations close to the absorption edge we get substantial HH–LH coupling because the exciton states consist of electron and hole states with k of the order of $1/a_B^*$, where a_B^* is the effective Bohr radius. The Coulomb coupling between different electron and hole states yields a second contribution to the mixing of single-particle states with different values of S_z. Finally, we must keep in mind that for higher excitation energies we get a superposition of exciton continua that are predominantly HH- or LH-like. These different excitons contribute oppositely to the spin orientation of electrons. We note that these arguments are valid for the optical excitation of bulk semiconductors and quasi-2D systems (Pfalz *et al*., 2005).

Optical orientation in bulk systems was reviewed by Dyakonov and Perel (1984). Early works on 2D systems were published by Weisbuch *et al*. (1981) and Masselink *et al*. (1984) who reported on polarization-resolved transmission and PL experiments on GaAs/AlGaAs quantum wells (QWs) under cw excitation. In later works, the electron-spin polarization in quasi-2D systems was studied using time-resolved PL excitation spectroscopy. For excitation energies even slightly above the HH resonance, several authors (Freeman, Awschalom and Hong, 1990; Dareys *et al*., 1993; Muñoz, Pérez, Viña and Ploog, 1995) observed a polarization that was significantly smaller than one. These measurements were carried out on fairly narrow GaAs/AlGaAs QWs. A first well-width dependent study of optical orientation was performed experimentally by Roussignol *et al*. (1992). For energies near the HH resonance, they found initial spin polarizations in the range of 60–80%.

Twardowski and Hermann (1987) as well as Uenoyama and Sham (1990) studied the polarization of QW PL theoretically, taking into account HH–LH coupling in

the valence band. However, these authors neglected the Coulomb interaction between electron and hole states. On the other hand, Maialle, de Andrada e Silva and Sham (1993) investigated the spin dynamics of excitons taking into account the exchange coupling between electrons and holes, but disregarded the HH–LH coupling in the valence band. Recently, a detailed experimental and theoretical study of optical orientation in 2D systems was performed by Pfalz *et al*. (2005) confirming that the polarization of the measured PL reflects the spin polarization of the excited electrons (equation (1)) over a wide range of excitation energies. As an example, Figure 2 shows the measured and calculated degree of spin polarization P as a function of excitation energy of a 198-Å-wide GaAs/AlAs QW.

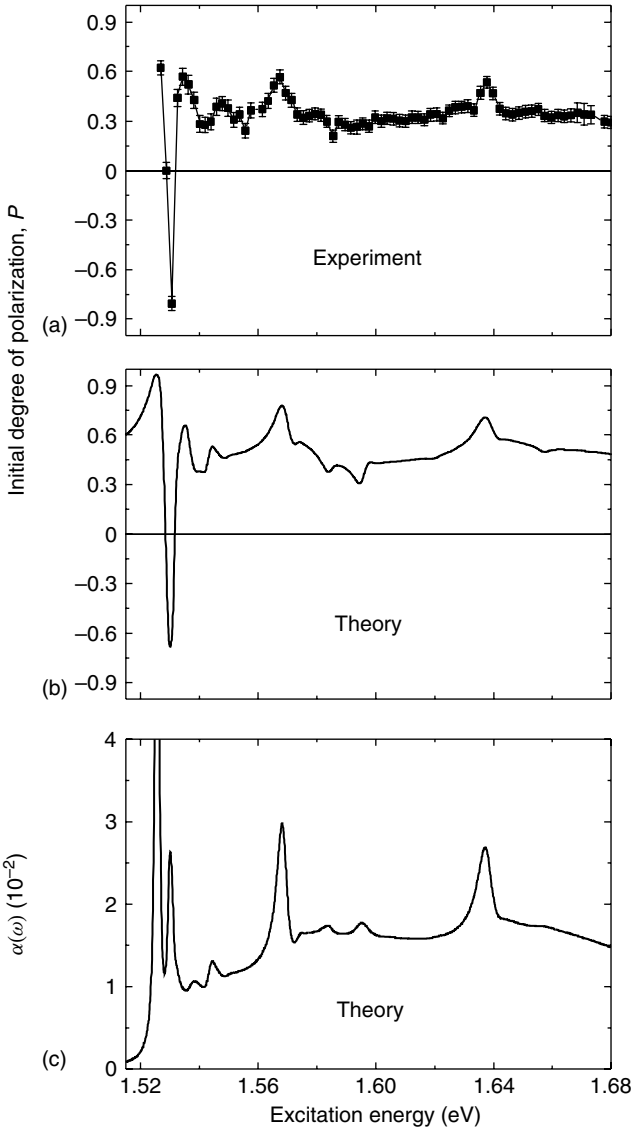

Figure 2. (a) Measured and (b) calculated degree of spin polarization P and (c) calculated absorption coefficient $\alpha(\omega)$ as a function of excitation energy of a 198-Å-wide GaAs/AlAs QW. The lowest peak in the absorption spectrum is an HH exciton that gives rise to a large positive spin orientation. The next peak slightly above the first peak is due to the LH exciton, and it results in a strongly negative spin orientation. The peaks at higher energies are Fano resonances, which give mixed contributions to the spin polarization. (Adapted from Pfalz *et al*., 2005.)

3 NONEQUILIBRIUM SPIN FLOW IN SEMICONDUCTORS

3.1 Spin drift and diffusion

Similar to electric charge distributions in semiconductors, a nonequilibrium spin distribution can spread out diffusively or it can drift in the presence of an electric field. However, these phenomena behave qualitatively different in p- and n-type semiconductors (D'yakonov and Perel', 1971a). In p-type semiconductors, only the spins of the nonequilibrium electrons become oriented. Their number is proportional to the intensity of the light, but the degree of orientation does not depend on the intensity (Figure 1). As drift and diffusion of the spin orientation must preserve charge neutrality, the kinetics of the spin orientation follows the kinetics of the charge distribution. Charge diffusion in doped semiconductors is characterized by the diffusion coefficient of the minority carriers (Smith, 1978). Therefore, electron-spin diffusion in p-type semiconductors is essentially characterized by the charge diffusion coefficient for electrons[1].

In n-type semiconductors, the situation is qualitatively different due to the fact that the optically excited electrons augment the equilibrium electrons (D'yakonov and Perel', 1971a). Therefore, significant optical orientation of electron spins is possible at moderate degrees of excitation when the excess photoelectron density is still much less than the equilibrium electron density. The mechanism underlying this effect is the following. Absorption of circularly polarized light creates electrons with mainly a single spin orientation. The spin relaxation time τ_s of these electrons is typically much greater than the excess carrier lifetime. Holes, on the other hand, have a short spin relaxation time so that the spin orientation of the optically created holes is quickly lost. Therefore, *any* electron can recombine with these holes with a recombination rate that is usually independent of the sign of the spin. Thus, optical excitation is a source for spin-polarized electrons whereas recombination represents a drain for electrons with the 'wrong' spin orientation. Under stationary excitation, the oriented electrons are the equilibrium ones.

In a bulk sample, the light is usually absorbed in a narrow layer near the surface of the crystal. In this case, the excess

carriers penetrate a distance of the order of the diffusion length $L = \sqrt{D_p \tau}$, where D_p is the hole diffusion coefficient in the n-type sample (which is usually small), and τ is the lifetime of the nonequilibrium carriers. On the other hand, the orientation penetrates a depth of the order of the spin-diffusion length $L_s = \sqrt{D_s \tau_s}$, where D_s is the spin-diffusion coefficient of the electrons (which is usually large; it is approximately equal to the electron diffusion coefficient D_e). Under typical experimental conditions we thus have $L_s \gg L$ in an n-type sample (D'yakonov and Perel', 1971a). Beyond a layer of thickness $\sim L$, recombination cannot change the degree of polarization P that falls off like $P(z) = P(0)\exp(-z/L_s)$, that is, a spin orientation of the order of $P(0)$ penetrates into a layer of depth $\sim L_s$, where there are no excess carriers. (A small number of photoexcited carriers can be present within this layer because of reabsorption (Dzhioev, Zakharchenya, Korenev and Stepanova, 1997).)

In general, the motion of the spin density $\mathbf{S}$ is characterized by a drift-diffusion equation (D'yakonov and Perel', 1976; Garbuzov, Merkulov, Novikov and Fleisher, 1976; Dyakonov and Perel, 1984)

$$\frac{\partial \mathbf{S}}{\partial t} = D_s \nabla^2 \mathbf{S} + \frac{e\mathcal{E} \cdot \nabla \mathbf{S}}{k_B T} + \mathbf{\Omega} \times \mathbf{S} - \frac{\mathbf{S}}{\tau_s} - \frac{\mathbf{S} - \mathbf{S}_0}{\tau} \quad (2)$$

similar to the drift and diffusion of charge. Here $\mathcal{E}$ is a built-in or external electric field; T is the temperature; and Ω is the spin precession frequency, which can be due to an external magnetic field $\mathbf{B}$, that is, $\mathbf{\Omega} = g^* \mu_B \mathbf{B}/\hbar$, or due to spin-orbit coupling at $B = 0$ (see Section 3.2). The last two terms reflect two reasons for the spin orientation to vanish, spin relaxation and recombination, where $\mathbf{S}_0$ is the average spin orientation at the moment of photocreation. Recently, the drift-diffusion equation (2) was reconsidered by Flatté and Byers (2000) and Yu and Flatté (2002).

Spin drift and diffusion have been studied experimentally by several groups. Dzhioev, Zakharchenya, Korenev and Stepanova (1997) estimated that the spin diffusion length in their n-type GaAs sample was $L_s = 10\,\mu\text{m}$. Hägele *et al.* (1998) found that the spin orientation in intrinsic GaAs was almost completely preserved over a distance of $4\,\mu\text{m}$. Kikkawa and Awschalom (1999) performed a detailed study of spin transport in intrinsic and n-type GaAs samples in which gates allowed one to stir the drift of the spin-polarized electrons. Using nonlocal Faraday rotation, they found that the drift distance of the spin-oriented electrons was linear in the electric field, and it could exceed a distance of $100\,\mu\text{m}$ for electric fields of $16\,\text{V cm}^{-1}$. Fiederling *et al.* (1999) used semimagnetic $\text{Be}_x\text{Mn}_y\text{Zn}_{1-x-y}\text{Se}$ to inject spin-polarized electrons into a 0.1-μm-thick layer of n-type AlGaAs followed by a 15-nm-wide GaAs, where the spin-polarized electrons recombined with holes that were injected from the other side of the QW (a spin light-emitting diode). Similar experiments were also performed by Jonker *et al.* (2000) and Ohno *et al.* (1999) who used semimagnetic ZnMnSe and ferromagnetic GaMnAs, respectively, to create spin-polarized electrons that were injected into a nonmagnetic layer followed by a light-emitting diode[2].

It has been found that interfaces between different semiconductors do not affect spin transport. This was first noticed by Garbuzov, Merkulov, Novikov and Fleisher (1976), who studied spin orientation for a sample that contained a GaAs QW embedded in thick graded layers of p-type $\text{Al}_x\text{Ga}_{1-x}\text{As}$. Malajovich *et al.* (2000) found that even the interface between ZnSe and GaAs, a II–VI and a III–V semiconductor, did not suppress spin transport.

Lateral spin diffusion was studied by Cameron, Riblet and Miller (1996). When two laser beams with crossed polarizations interfere, the light intensity on the sample is uniform, but the polarization alternates between left polarized, linear, and right polarized. Therefore, a spin grating is generated in the sample where the optical orientation of the electrons alternates across the excitation region. By analyzing the orientation decay as a function of time, these authors could determine the spin-diffusion coefficient D_s and the spin relaxation time τ_s. The spin-diffusion length $L_s = \sqrt{D_s \tau_s}$ appeared to be approximately $8\,\mu\text{m}$ (Kavokin, 2002). Stotz, Hey, Santos and Ploog (2005) achieved a controlled lateral spin transport using two interfering traveling beams of coherent acoustic phonons. These beams resulted in dynamic quantum-dot like confining potentials that could take along the spin-polarized electrons.

3.2 Spin precession

The magnetic-field-dependent term $\mathbf{\Omega} \times \mathbf{S}$ in equation (2) describes the precessional motion of the oriented spins in an external field $\mathbf{B}$ or an effective field due to spin-orbit coupling. For a transverse external field $\mathbf{B}$, this term gives rise to the Hanle effect, a depolarization of luminescence induced by the field $\mathbf{B}$ (Dyakonov and Perel, 1984). In a homogenous system (i.e., $\nabla \mathbf{S} = 0$ in equation (2)), we get the expression for the Hanle curve

$$S_z(B) = \frac{S_z(0)}{1 + (\Omega T_s)^2}, \quad \text{where} \quad S_z(0) = \frac{S_0}{1 + \tau/\tau_s} \quad (3)$$

Here we have assumed that the z direction is the direction of the exciting radiation with $\mathbf{S}_0 \perp \mathbf{B}$, and T_s is the 'spin lifetime' defined by $T_s^{-1} = \tau^{-1} + \tau_s^{-1}$. From the Hanle curve as a function of field B, one can thus extract the lifetime τ and the spin relaxation time τ_s of the carriers (provided the effective Landé factor g^* is known). However,

a particular situation arises in n-type semiconductors where recombination is not possible past the surface layer of thickness $\sim L$. The depolarization induced by the magnetic field thus changes the gradient of the degree of polarization within the layer where electrons are oriented. Therefore, the spin-diffusion rate becomes magnetic-field-dependent, which results in a distinct change of the functional form of the Hanle curve as a function of magnetic field (D'yakonov and Perel', 1976).

In the presence of both time-inversion symmetry and space-inversion symmetry, all electron states in a solid with a given wave vector $\mathbf{k}$ are twofold degenerate. When the potential through which the carriers move is inversion-asymmetric, however, the spin degeneracy is removed even in the absence of an external magnetic field B. We then obtain two branches of the energy dispersion, $E_+(\mathbf{k})$ and $E_-(\mathbf{k})$. This spin splitting can be the consequence of a bulk inversion asymmetry (BIA) of the underlying crystal (e.g., a zinc blende structure; Dresselhaus, 1955), and of a structure inversion asymmetry (SIA) of the confinement potential (Ohkawa and Uemura, 1974; Bychkov and Rashba, 1984). Strain gives rise to a third contribution to $B = 0$ spin splitting (Seiler, Bajaj and Stephens, 1977; Howlett and Zukotynski, 1977). A fourth contribution can be the low microscopic symmetry of the atoms at an interface (Rössler and Kainz, 2002). $B = 0$ spin splitting has been reviewed, for example, by Pikus, Marushchak and Titkov (1988) and Winkler (2003). In the present context, it is important that the spin splitting can be ascribed to an effective Zeeman term $H = (\hbar/2)\boldsymbol{\sigma} \cdot \boldsymbol{\Omega}(\mathbf{k})$ with an effective magnetic field $\boldsymbol{\Omega}(\mathbf{k})$. In leading order of $\mathbf{k}$, the effective field in a 2D electron system on a (001) surface reads

$$\boldsymbol{\Omega}(\mathbf{k}_\parallel) = \frac{2\gamma}{\hbar} \begin{pmatrix} k_x \left(k_y^2 - \langle k_z^2 \rangle\right) \\ k_y \left(\langle k_z^2 \rangle - k_x^2\right) \\ 0 \end{pmatrix} + \frac{2\alpha}{\hbar} \begin{pmatrix} k_y \\ -k_x \\ 0- \end{pmatrix} \qquad (4)$$

The first term characterizes the BIA spin splitting of the electron states. It is called the *Dresselhaus* or k^3 term (Dresselhaus, 1955; Braun and Rössler, 1985). It exists already in bulk zinc blende semiconductors due to the broken inversion symmetry. In quasi-2D systems only the in-plane wave vector $\mathbf{k}_\parallel = (k_x, k_y, 0)$ is a continuous variable. In first-order perturbation theory, the wave vector components k_z and powers thereof are replaced by expectation values with respect to the subband wave functions. The field $\boldsymbol{\Omega}(\mathbf{k}_\parallel)$ due to BIA is depicted in Figure 3(a). We note that in 2D systems, the Dresselhaus term depends on the crystallographic orientation of the substrate. For 2D systems on an $[mmn]$ surface with integers m and n, the Dresselhaus term was given by Braun and Rössler (1985).

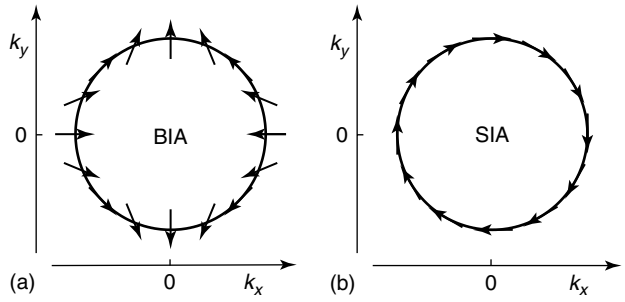

Figure 3. Effective magnetic field $\boldsymbol{\Omega}(\mathbf{k}_\parallel)$ along a contour of constant energy (a) due to the Dresselhaus term in a system with BIA and (b) due to the Rashba term in a system with SIA.

The momentum scattering of electrons off other electrons, impurities, phonons, etc., results in a random-walk type precession of the electron spins in the field $\boldsymbol{\Omega}(\mathbf{k})$, which gives rise to the so-called Dyakonov–Perel spin relaxation (D'yakonov and Perel', 1972; Pikus and Titkov, 1984). A *controlled* precession of electrons in the Dresselhaus field $\boldsymbol{\Omega}(\mathbf{k})$ was first demonstrated by Riechert *et al*. (1984), who investigated the polarization of photoemission following optical orientation. After deposition of Cs and O on the (110) surface of their strongly p-doped GaAs sample, a surface inversion layer was formed where the bands were strongly bent downward. Electrons moving through this layer gain a large kinetic energy. Yet if the layer is very narrow, they move ballistically with $\mathbf{k}$ normal to the surface so that the direction of $\boldsymbol{\Omega}$ is the same for all escaping electrons. The photoelectron orientation is thus rotated away from the initial direction defined by the pumping light beam, as observed by Riechert *et al*[3].

In asymmetric QWs, SIA gives rise to the second term in equation (4), which is frequently called the *Rashba* term (Rashba, 1960; Bychkov and Rashba, 1984). The coefficients γ and α depend on the underlying semiconductor bulk material; but α depends also on the asymmetry of the QW in the growth direction (Winkler, 2003). It can be tuned by means of front and back gates (Nitta, Akazaki, Takayanagi and Enoki, 1997). This is exploited in the famous spin-field-effect transistor proposed by Datta and Das (1990), see **Semiconductor Spintronic Devices, Volume 5**. The field $\boldsymbol{\Omega}(\mathbf{k}_\parallel)$ due to SIA is depicted in Figure 3(b).

A third contribution to $\boldsymbol{\Omega}(\mathbf{k})$ at $B = 0$ is obtained by means of strain. In lowest order of $\mathbf{k}$ and of the components ε_{ij} of the strain tensor we get (Pikus and Titkov, 1984)

$$\boldsymbol{\Omega}(\mathbf{k}) = \frac{C_3}{\hbar} \begin{pmatrix} \varepsilon_{xy}k_y - \varepsilon_{xz}k_z \\ \varepsilon_{yz}k_z - \varepsilon_{yx}k_x \\ \varepsilon_{zx}k_x - \varepsilon_{zy}k_y \end{pmatrix} + \frac{C_3'}{\hbar} \begin{pmatrix} k_x(\varepsilon_{yy} - \varepsilon_{zz}) \\ k_y(\varepsilon_{zz} - \varepsilon_{xx}) \\ k_z(\varepsilon_{xx} - \varepsilon_{yy}) \end{pmatrix} \qquad (5)$$

The first term depends on the off-diagonal components of the strain tensor, that is, these components describe a shear strain. They are nonzero, for example, when uniaxial stress is applied in the crystallographic directions [111] or [110] of a bulk crystal (Trebin, Rössler and Ranvaud, 1979). The prefactor C_3' of the second term in equation (5) is nonzero only because of coupling to remote bands outside the usual 8×8 Kane Hamiltonian. Therefore, this term is rather small, so usually it can be neglected (Pikus and Titkov, 1984; D'yakonov, Marushchak, Perel' and Titkov, 1986).

For bulk InSb, the effect of strain on spin splitting has been studied by measuring Shubnikov–de Haas oscillation (Seiler, Bajaj and Stephens, 1977) and cyclotron resonance (Ranvaud, Trebin, Rössler and Pollak, 1979). D'yakonov, Marushchak, Perel' and Titkov (1986) analyzed the Hanle effect in the presence of strain in order to obtain $C_3 = 20\,\text{eVÅ}$ for GaSb, $C_3 = 5\,\text{eVÅ}$ for GaAs, and $C_3 = 3\,\text{eVÅ}$ for InP. The decrease of these values from GaSb to InP correlates with the decrease in the spin-orbit interaction gap in these crystals from 0.82 to 0.11 eV.

The effect of strain on spin transport in *n*-type (001) GaAs was first studied by Kato, Myers, Gossard and Awschalom (2004a) using time and spatially resolved Faraday rotation spectroscopy. However, they did not quantify or tune the strain in their samples. The implications of equation (5) have been confirmed in detail in experiments by Crooker and Smith (2005). Similar experiments have been published also by Beck, Metzner, Malzer and Döhler, 2005. Crooker and Smith used a small vise to apply tunable uniaxial strain along the [110] or $[1\bar{1}0]$ direction of their *n*-GaAs sample, while a circularly polarized 1.58-eV laser focused to a 4-μm spot was used to create locally a spin orientation along [001]. In spatially resolved measurements using Kerr rotation they studied the electron-spin precession while the electrons drifted and diffused away from the position of the laser spot, where the spin orientation was created (see Figure 4).

Crooker and Smith found that the spin precession of electrons drifting and diffusing in the strain field (5) is more robust than the precession of electrons moving in an external magnetic field. The reason is that in a transverse magnetic field the ensemble spin orientation dephases quickly when the precession period falls below the spin-diffusion length (the Hanle effect discussed in the preceding text). The strain-induced field (5), on the other hand, is linear in the wave vector $\mathbf{k}$ so that slowly moving electrons experience a smaller field $\boldsymbol{\Omega}(\mathbf{k})$ than the faster electrons. But the distance the electrons must travel for a complete precession period is the same for slow and fast electrons so that the electrons remain in phase (Figures 4c and d). This argument also implies that the precession period should be independent of the magnitude of the external electric field used to push the electrons, as

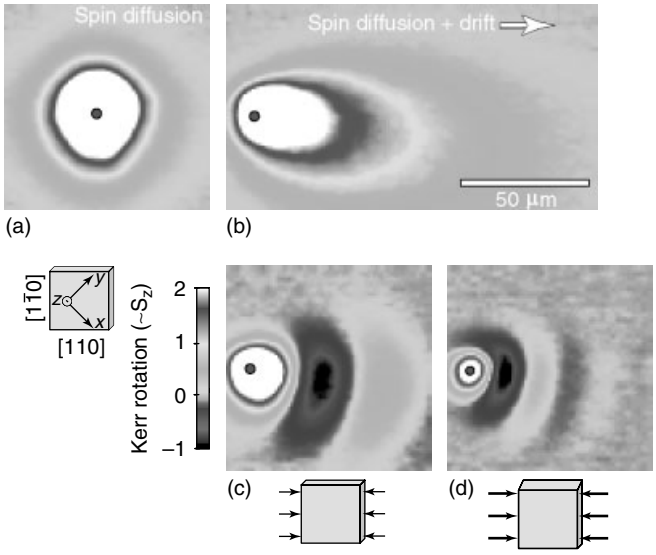

Figure 4. Images of the electron-spin flow in a 1-μm-thick *n*-GaAs epilayer ($n = 1 \times 10^{16}\,\text{cm}^{-3}$) at 4 K, acquired via Kerr-rotation microscopy. (a) Shows the spin polarization due to spin diffusion alone. In (b)–(d), a lateral electric field $E = 10\,\text{V cm}^{-1}$ was applied. Finally, E was complemented by (c) weak and (d) large uniaxial stress along [110]. The white bar in (b) gives the length scale for all four panels. (Adapted from Crooker and Smith, 2005.)

confirmed by the experiments of Crooker and Smith and Beck, Metzner, Malzer and Döhler.

The strain-induced field (5) has a pronounced dependence on the wave vector $\mathbf{k}$. If a uniaxial strain is applied along the direction [110], we have $\Omega = 0$ for $\mathbf{k}$ along [001]. This is analogous to the fact that we have no Dresselhaus spin splitting in symmetric QWs on a (110) surface for $\mathbf{k}_\parallel$ along [001] (Winkler, 2003). Within the (001) plane the $\mathbf{k}$ dependence of $\boldsymbol{\Omega}$ is the same as for the Rashba term, see Figure 3(b). If, in addition to the strain-induced field (5) an external magnetic field $\mathbf{B}$ is applied, the electrons with $\boldsymbol{\Omega}(\mathbf{k})$ approximately parallel to $\mathbf{B}$ precess faster than the electrons with $\boldsymbol{\Omega}(\mathbf{k})$ approximately antiparallel to $\mathbf{B}$. This was confirmed by the experiments of Crooker and Smith. To show this they used the fact that the radial diffusion in a pure strain-induced field (5) *or* an external magnetic field $\mathbf{B}$ is independent of the direction of $\mathbf{k}$, which reflects the fact that the magnitude of $\boldsymbol{\Omega}$ does not depend on the direction of the $\mathbf{k}$ vector of the electrons. The superposition of both fields, on the other hand, results in an anisotropic total field $\boldsymbol{\Omega}$ the magnitude of which depends on the direction of $\mathbf{k}$. This is similar to the fact that, to lowest (i.e., linear) order in $\mathbf{k}_\parallel$, the magnitude of both the Dresselhaus and Rashba spin splitting in 2D systems are independent of the direction of $\mathbf{k}_\parallel$ (see Figure 3), yet the superposition of both terms gives rise to anisotropic spin splitting even in linear order of $\mathbf{k}_\parallel$ (de Andrada e Silva, 1992).

The interplay of diffusion, drift in electric fields, and precession in external magnetic fields was studied theoretically by Qi and Zhang (2003) using a semiclassical Boltzmann equation for the 2×2 spin density matrix in order to cope with the different length scales of this problem, such as the diffusion length L, the spin-diffusion length L_s, and the spin precession length. Spin diffusion equations for systems with Rashba spin-orbit interaction in an electric field were studied by Bleibaum (2006). Drift and diffusion were also studied theoretically by Hruška *et al*. (2006) for an experimental setup similar to the one used by Crooker and Smith (2005) as described in the preceding text.

3.3 Coulomb effects

So far, we have completely neglected the Coulomb interaction between the electrons. Although this interaction does not couple to the spin degree of freedom of the electrons, it has a great influence on spin-dependent transport. This has long been known in the context of spin diffusion in spin-polarized liquid ^{3}He. Leggett and Rice (1968) and Leggett (1970) have shown that the spin polarization gives rise to a molecular field, and any given spin will then see (and precess around) a total field that is the sum of the molecular field and the external field. This molecular field cannot affect the precession of the total spin density $\mathbf{S}$, since it is automatically parallel to it. However, it produces a torque on the spin current, which is present in the equation of continuity for the latter. Leggett showed that, as a result, the equation for $\mathbf{S}$ in the hydrodynamic limit no longer has a simple form similar to equation (2) but he derived a significantly more complicated hydrodynamic-type spin-diffusion equation. More recently, Takahashi, Shizume and Masuhara (1999) have applied these ideas to the spin diffusion and drift in 2D electron systems. They solved the quantum kinetic equation derived from the equation of motion for the nonequilibrium real-time Green's functions in order to show that the spin rotation term known for ^{3}He is indeed also present in degenerate 2D electron systems at low temperatures.

In a sequence of papers, D'Amico and Vignale (2000, 2001, 2002, 2003) performed a detailed theoretical analysis of how the Coulomb interaction affects spin-polarized transport and diffusion in electron systems (see also Flensberg, Jensen and Mortensen (2001)). D'Amico and Vignale showed that the Coulomb interaction gives rise to a spin Coulomb drag between the electrons moving with spin up and the electrons moving with spin down, similar to the Coulomb drag that has been observed for electrons in two spatially separated layers (Gramila *et al*., 1991; Rojo, 1999). The spin Coulomb drag reflects the fact that while, in the absence of impurities, the total momentum $\mathbf{P} = \sum_i \mathbf{p}_i$ of the electrons is preserved, the 'up' and 'down' components of the total momentum, $\mathbf{P}_\uparrow = \sum_i \mathbf{p}_i(1 + \sigma_{zi})/2$ and $\mathbf{P}_\downarrow = \sum_i \mathbf{p}_i(1 - \sigma_{zi})/2$, are not separately preserved, even in the absence of impurities. Here $\mathbf{p}_i$ is the momentum of the ith electron, and σ_{zi} is the Pauli matrix for the z component of the ith electron spin. Coulomb scattering can transfer momentum between spin-up and spin-down electrons, thereby effectively introducing a 'friction' for the relative motion of the two spin components, which tends to equalize the net momenta of the spin components (see Figure 5).

In a more rigorous formulation, Ohm's law can be written in the form

$$\begin{pmatrix} \mathcal{E}_\uparrow \\ \mathcal{E}_\downarrow \end{pmatrix} = \begin{pmatrix} \rho_{\uparrow\uparrow} & \rho_{\uparrow\downarrow} \\ \rho_{\downarrow\uparrow} & \rho_{\downarrow\downarrow} \end{pmatrix} \begin{pmatrix} \mathbf{j}_\uparrow \\ \mathbf{j}_\downarrow \end{pmatrix} \tag{6}$$

Here, the effective electric fields $\mathcal{E}_\sigma$ are the sums of a spin-independent external electric field plus the gradient of the local chemical potential, which can be spin-dependent, and $\mathbf{j}_\sigma$ is the electric current carried by the electrons with spin σ. The spin Coulomb drag gives rise to a spin transresistivity $\rho_{\uparrow\downarrow}$ in equation (6), which is the ratio of the gradient of the spin-down electrochemical potential to the spin-up current density when the spin-down current is zero. D'Amico and Vignale (2000) evaluated $\rho_{\uparrow\downarrow}$ in a generalized random-phase approximation.

D'Amico and Vignale (2001) showed that the Coulomb interaction usually gives rise to a significant reduction of the spin-diffusion coefficient D_s in equation (2) as compared to its value D_{ni} in a noninteracting system. They obtained

$$D_s = \frac{\mu k_{\mathrm{B}} T}{e} \frac{\mathcal{S}}{\mathcal{S}_c} \frac{1}{1 - \rho_{\uparrow\downarrow}/\rho_{\mathrm{D}}} \tag{7}$$

where $\mu k_{\mathrm{B}} T/e$ is the diffusion constant of a noninteracting system in the high-temperature limit (Einstein's relation), $\mathcal{S}$ is the spin stiffness (i.e., the inverse of the spin

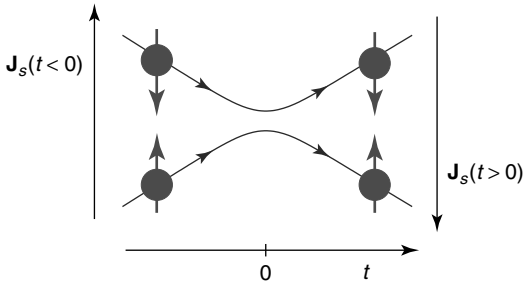

Figure 5. At $t < 0$ both electrons contribute equally to an upward spin current $\mathbf{J}_s = (e/m)(\mathbf{P}_\uparrow - \mathbf{P}_\downarrow)$. At $t = 0$, the directions of the orbital motions of the electrons are inverted due to Coulomb scattering. The direction of the spin current $\mathbf{J}_s$ at $t > 0$ is thus reversed.

susceptibility), $\mathcal{S}_c = k_B T n/(4n_\uparrow n_\downarrow)$ is the Curie spin stiffness of an ideal classical gas, and $\rho_D = m^*/(ne^2\tau_D)$ is the Drude resistivity. Figure 6 shows the ratio D_s/D_{ni} as a function of density n, assuming a dielectric constant $\varepsilon = 12$ appropriate for GaAs and mobility $\mu = 3 \times 10^3\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$. Different line styles correspond to different temperatures as indicated. The curves labeled SD correspond to the case in which interactions in D_s are taken into account only through the spin Coulomb drag (i.e., the third factor in equation (7)).

Figure 6 shows that the interaction correction is quite significant and reduces the value of D_s. For large densities or $T \lesssim T_F$, where T_F is the Fermi temperature for density n, the dominant effect in the full calculation stems from the softening of the spin stiffness. On the other hand, the spin drag contribution dominates at small densities (the nondegenerate limit $T \gg T_F$). Note that $T_F = 1.6$, 20, and 300 K correspond to $n = 7.4 \times 10^{15}$, 3.2×10^{17}, and $1.9 \times 10^{19}\,\mathrm{cm^{-3}}$, respectively.

The spin Coulomb drag in a 2D electron gas was studied theoretically by D'Amico and Vignale (2003) and Flensberg, Jensen and Mortensen (2001), giving results quantitatively similar to three-dimensional (3D) electron systems. It was also observed experimentally by Weber *et al*. (2005). These authors used spin gratings as discussed at the end of Section 3.1 to measure the spin-diffusion coefficient D_s in a 2D electron gas in a GaAs/AlGaAs QW (circles in Figure 7). Its value as a function of temperature is significantly smaller than the charge diffusion coefficient D_c obtained from transport measurements for samples from the same wafer (solid lines in Figure 7). Yet good agreement is achieved between the measured D_s and calculations taking into account the spin Coulomb drag effect (i.e., the last factor in equation (7)), see the dashed line in Figure 7.

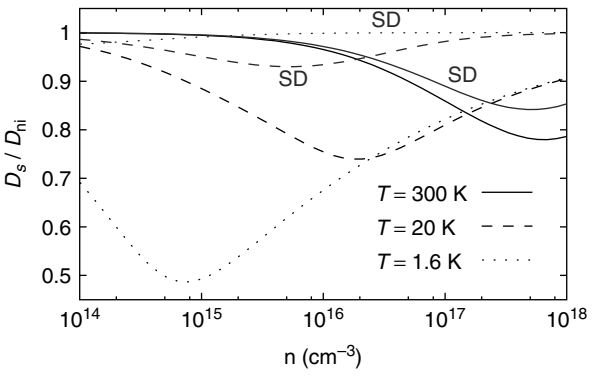

Figure 6. Ratio D_s/D_{ni} between the spin-diffusion coefficient D_s of an interacting electron system and the spin-diffusion coefficient D_{ni} of the corresponding noninteracting system, plotted as a function of density n, and assuming a dielectric constant $\varepsilon = 12$ appropriate for GaAs and mobility $\mu = 3 \times 10^3\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$. The curves labeled SD correspond to the case in which interactions in D_s are taken into account only through the spin Coulomb drag (i.e., the third factor in equation (7)). 4 SPIN POLARIZATION AND CHARGE CURRENTS

4.1 Spin photocurrents

The optical creation of spin-oriented electrons can give rise to charge currents, the so-called spin photocurrents, which are characterized by the fact that these currents reverse their direction when the radiation helicity is changed from left-handed to right-handed and vice versa. Spin photocurrents are described by an axial tensor (or pseudotensor) of second rank. Such tensors play an important role in the context of gyrotropy, so that systems permitting nonzero axial second-rank tensors are often denoted gyrotropic systems. We note that gyrotropy is found neither in inversion-symmetric systems nor in systems with a zinc blende structure. The 18 gyrotropic crystal classes are listed, for example, by Agranovich and Ginzburg (1984)[4]. Semiconductors with a zinc blende (or diamond) structure become gyrotropic when the symmetry is reduced by means of, for example, quantum confinement or uniaxial strain. We note that gyrotropy is also a required and sufficient condition for the existence of k-linear spin splitting of the energy spectrum of spin-1/2 electron systems.

Two mechanisms contribute to spin photocurrents in gyrotropic media, the circular photogalvanic effect (CPGE) and the spin-galvanic effect (SGE) (Ganichev and Prettl, 2003). The CPGE was independently predicted by Ivchenko

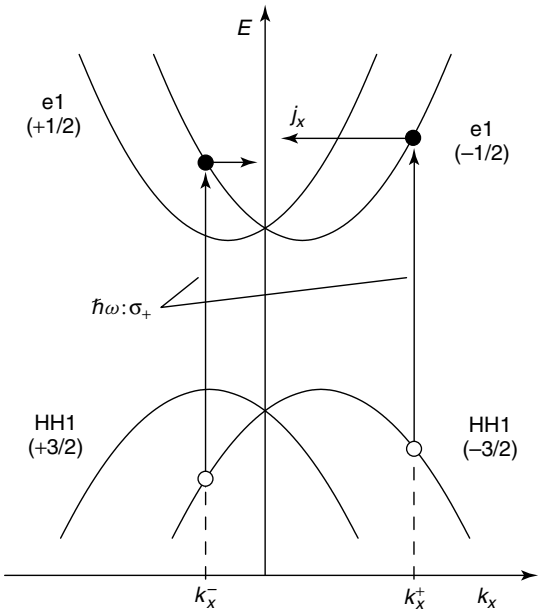

Figure 8. Microscopic picture of the circular photogalvanic effect (after Ganichev *et al*. (2001)). σ_+ excitation with photon energy $\hbar\omega$ induces optical transitions between the valence subband hh1 and the conduction subband e1 (vertical arrows). The concurrence of energy conservation, spin splitting of the electron and hole states, and optical selection rules results in an unbalanced occupation of the positive (k_x^+) and negative (k_x^-) states yielding a spin-polarized photocurrent. (Reprinted from *Journal of Magnetism and Magnetic Materials*, vol 300, Ganichev *et al*., p127, 2006 with permission from Elsevier.)

and Pikus (1978) and Belinicher (1978). Subsequently, this effect was observed in bulk Te by Asnin *et al*. (1978). The mechanism is illustrated in Figure 8. Excitation with σ_+-polarized light induces direct optical transitions between the valence subband hh1 and the conduction subband e1 (vertical arrows in Figure 8). For a given photon energy $\hbar\omega$, the optical selection rules and spin splitting result in an unbalanced occupation of the positive (k_x^+) and negative (k_x^-) states such that the 'center of mass' of these transitions is shifted from $k_x = 0$ to some average value $\langle k_x \rangle \neq 0$. This wave vector $\langle k_x \rangle$ translates into an average electron velocity $v = \hbar\langle k_x \rangle / m^*$ of the optically oriented electrons, which corresponds to a spin-polarized charge current, that is, the current is carried by electrons with one spin orientation. For interband transitions in 2D systems, as depicted in Figure 8, a detailed theory for the CPGE has been formulated by Golub (2003). Spin photocurrents can also be generated in a similar way by means of intersubband and intrasubband transitions (Ganichev *et al*., 2001; Ganichev and Prettl, 2003). Sherman, Najmaie and Sipe (2005) and Tarasenko and Ivchenko (2005) have shown that pure spin photocurrents not accompanied by charge transfer or spin orientation can be generated by means of absorption of unpolarized light in low-dimensional semiconductor systems.

Up to now, we have discussed spin photocurrents obtained by means of one-photon absorption. These currents can also be generated by means of two-photon excitation (Bhat and Sipe, 2000). In this case, the spin polarization of the resulting charge currents has been confirmed directly by measuring the phase-dependent spatial shift of the circularly polarized PL (Hübner *et al*., 2003). Pure spin photocurrents not accompanied by charge transfer have been generated through quantum interference of one- and two-photon absorption by Stevens *et al*. (2003).

Besides the CPGE, the SGE is a second mechanism that contributes to spin photocurrents (Ivchenko, Lyanda-Geller and Pikus, 1989; Ganichev *et al*., 2002). The SGE is caused by asymmetric spin-flip relaxation of spin-polarized electrons. The mechanism is illustrated in Figure 9. An unbalanced population of spin-up and spin-down subbands is generated, for example, by optical orientation. The current flow is caused by **k**-dependent spin-flip relaxation processes. Spins oriented in the up direction are scattered along k_x from the more occupied, for example, spin-up branch, to the less filled spin-down branch. Four quantitatively different spin-flip scattering events exist and are sketched in Figure 9 as bent arrows. The spin-flip scattering rate depends on the values of the wave vectors of the initial and the final states. Therefore, the spin-flip transitions marked by solid arrows in Figure 9 have the same rates. They preserve the distribution of carriers in the branches and, thus, do not yield a current. However, the two scattering processes shown by dashed arrows are inequivalent and generate an asymmetric carrier distribution around the branch minima. This asymmetric population results in a current flow along the x-direction. Within this model of elastic scattering the current is not spin polarized, since the same number of spin-up and spin-down

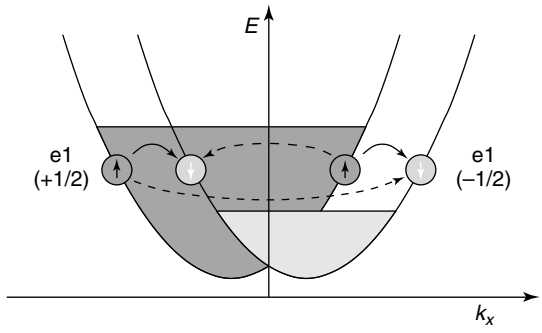

Figure 9. One-dimensional microscopic picture of the spin-galvanic effect (after Ganichev *et al*. (2001)). If one spin subband is preferentially occupied, for example, by optical excitation, asymmetric spin-flip scattering results in a current in the x direction.

electrons move in the same direction with the same velocity (Ganichev *et al*., 2002).

Assuming a linear relation between the components S_β of the electrons' averaged spin density and the components j_α of the resulting spin photocurrent, we get for the SGE

$$j_\alpha = \sum_\beta \mathcal{T}_{\alpha\beta} S_\beta \qquad \alpha, \beta = x, y, z \tag{8}$$

where $\mathcal{T}_{\alpha\beta}$ is an axial tensor of second rank[5]. This equation shows clearly that, unlike the case of the CPGE, optical excitation is not required for the SGE. The CPGE, however, is always accompanied by the SGE. Formally, this is due to the fact that both effects are characterized by axial tensors of second rank. Even in a completely optical experiment, CPGE and SGE can be distinguished by their different behaviors when the light source is switched off. Then the circular photogalvanic current decays with the momentum relaxation time whereas the spin-galvanic current decays with the spin relaxation time. If spin relaxation is absent, the spin-galvanic current vanishes (Ganichev and Prettl, 2003).

In recent years, detailed experimental and theoretical investigations of the CPGE and SGE in different systems have been performed by Ganichev *et al*. This work and related work have been reviewed by Ganichev and Prettl (2003, 2006).

4.2 Electrical generation of a spin polarization

In general, two possibilities exist for orienting electron spins with electric currents in a semiconductor. The first one is the spin Hall effect. For semiconductor systems, this idea was first discussed by D'yakonov and Perel' (1971b). It yields a spin accumulation at the *edges* of the sample in the direction perpendicular to the current. A detailed discussion of the spin Hall effect can be found in **Theory of Spin Hall Effects in Semiconductors, Volume 5**. In gyrotropic media, a second mechanism exists that yields a spin polarization in the *bulk* of the sample (Aronov and Lyanda-Geller, 1989; Edelstein, 1990). We note that equation (8), relating the given spin orientation $\mathbf{S}$ with the resulting current $\mathbf{j}$, can obviously be inverted, that is, an electric current $\mathbf{j}$ can give rise to a spin density $\mathbf{S}$ (Ivchenko and Pikus, 1978). As discussed in detail by Aronov, Lyanda-Geller and Pikus (1991), the different mechanisms contributing to the spin polarization of electrons induced by a current $\mathbf{j}$ can be classified analogously to the different spin relaxation mechanisms for $\mathbf{j} = 0$: for $\mathbf{j} = 0$, these mechanisms drive the system toward its equilibrium configuration characterized by equal occupations of the spin states. For $\mathbf{j} \neq 0$, on the other hand, the nonequilibrium configuration is characterized by an unequal filling of the spin states. Apart from a prefactor Q of order one, the details of which depend on the scattering mechanisms present in the electron system, the spin polarization is given by the ratio between the spin splitting $\hbar\Omega(\mathbf{k}_\mathcal{E})$ (assumed to be linear in $\mathbf{k}$) and the average energy $\overline{E}$ of the involved electrons (Aronov, Lyanda-Geller and Pikus, 1991)

$$\mathbf{S} = Qn \frac{\hbar\mathbf{\Omega}(\mathbf{k}_\mathcal{E})}{\overline{E}} \tag{9}$$

Here $\mathbf{k}_\mathcal{E} = e\mathcal{E}\tau_p/\hbar$ is the shift of the Fermi sphere caused by the electric field $\mathcal{E}$, and τ_p is the momentum relaxation time. In degenerate systems, we have $\overline{E} = \hbar^2 k_\mathrm{F}^2/(2m^*)$. In nondegenerate systems we have $\overline{E} = (d/2)k_\mathrm{B}T$, where d is the dimension. Finally, $n = k_\mathrm{F}^d/(d\pi)$ is the number density. The prefactor Q for different scattering mechanisms in $d = 2$ and $d = 3$ dimensions is given in Table I of Aronov, Lyanda-Geller and Pikus (1991).

The electric-field-induced spin orientation inside a semiconductor was also studied theoretically by Magarill, Chaplik and Éntin (2001) in 2D and Culcer, Yao, MacDonald and Niu (2005) in 2D and 3D. The effect was first observed experimentally in bulk Te by Vorob'ev *et al*. (1979). More recently, it was used by Hammar, Bennett, Yang and Johnson (1999, 2000) to analyze the spin injection from a ferromagnetic film into a 2D electron system, see also Monzon, Tang and Roukes (2000) van Wees (2000) and Silsbee (2001). Moreover, the effect was measured in strained bulk InGaAs by Kato, Myers, Gossard and Awschalom (2004b) and in 2D GaAs systems by Silov *et al*. (2004) and Ganichev *et al*. (2004, 2006). As an example, we want to discuss the experiment of Ganichev *et al*. They used a p-type GaAs multi-QW grown on an intentionally miscut (001) surface (tilted by 5° toward the [110] direction). The symmetry of this system is thus fully characterized by one mirror plane $(1\bar{1}0)$ (i.e., point group C_s), and electric spin orientation is expected only for a current in the ('active') direction $[1\bar{1}0]$ of the 2D plane, but not for the perpendicular ('passive') direction. In a transmission measurement using linearly polarized light, it is then possible to identify the current-induced spin orientation via a rotation of the polarization vector of the transmitted light (dichroic absorption and Faraday rotation) in a crossed polarizer setup, see the inset of Figure 10. For the 'active' direction $[1\bar{1}0]$, Ganichev *et al*. observed a significantly larger signal in the photodetector than for the 'passive' direction (Figure 10). The nonzero signal for the 'passive' direction was ascribed to imperfections of the infrared polarizers and carrier heating by the current, as confirmed by control experiments.

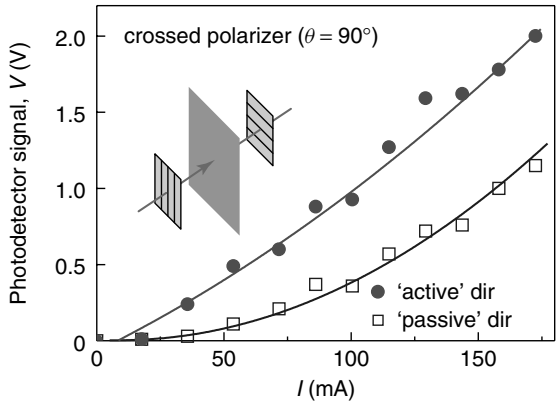

Figure 10. Transmission of a GaAs multi-QW as a function of current I in a crossedpolarizer setup (sketched in the inset). The sample was grown on a miscut (001) surface so that spin orientation is expected for the 'active' direction $[1\bar{1}0]$ but not for the perpendicular 'passive' direction. (Reproduced from Ganichev *et al*., 2006, with permission from Elsevier. © 2006.)

Finally, we note that Kalevich and Korenev (1990) predicted and observed a current-induced spin precession in the field $\mathbf{\Omega}(\mathbf{k}_{\mathcal{E}})$.

5 OUTLOOK

We focused here on the fundamental physics underlying the spin-dependent transport of carriers in semiconductors. These phenomena have many important and fascinating applications in the field of spintronics that are discussed elsewhere in this volume. Particularly important are various laterally structured systems such as the Datta-Das spin transistor (Datta and Das, 1990) and hybrid devices combining nonmagnetic semiconductors with semimagnetic and ferromagnetic materials.

ACKNOWLEDGMENTS

The author appreciates stimulating discussions with M. Beck, D. Culcer, S. D. Ganichev, and L. E. Golub. Also, he is grateful to S. A. Crooker for Figure 4. NOTES

[1] When a semiconductor has a large absorption coefficient near the band edge, an emitted photon is usually reabsorbed before it can escape the crystal (Dumke, 1957). The detailed analysis of spin diffusion in p-type semiconductors performed by Garbuzov, Merkulov, Novikov and Fleisher (1976) and Gioev, Zakharchenya, Kavokin and Pak (1994) showed that allowance for diffusion and reabsorption was essential for the proper interpretation of their experimental data. Even in n-type GaAs it was found that reabsorption can be important for spin diffusion (Dzhioev, Zakharchenya, Korenev and Stepanova, 1997). Please note that the first authors of the latter two publications are, in fact, the same.

[2] The broad field of spin injection into semiconductors was recently reviewed, for example, by Jonker (2003).

[3] The Rashba spin splitting discussed below was not taken into account by Riechert, Alvarado, Titkov and Safarov (1984) for the interpretation of their experiment. However, this does not change the qualitative picture.

[4] As certain aspects of gyrotropy require a symmetric material tensor, the discussion of gyrotropy is often restricted to those 15 crystal classes that permit a symmetric axial tensor of second rank (Nye, 1957; Landau and Lifshitz, 1984), thus excluding the crystal classes C_{3v}, C_{4v}, and C_{6v} (the latter includes wurtzite materials). Spin photocurrents and the electric generation of spin discussed below do not require that the corresponding material tensors are symmetric. Therefore, these effects can be observed for all 18 crystal classes that permit an axial tensor of second rank. A general discussion of the symmetry of material tensors was given, for example, by Bir and Pikus (1974).

[5] For many crystal classes permitting nonzero axial tensors of second rank it is nonetheless required by symmetry that certain components of these tensors must vanish, see, for example, the discussion of the experiment of Ganichev *et al*. (2004, 2006) in Section 4.2 below.

Semiconductor Spintronic Devices

Michael E. Flatté
University of Iowa, Iowa City, IA, USA

1 INTRODUCTION

Semiconductors, more than any other class of material, are very sensitive to external electrical perturbations, and as a result the properties of a semiconducting material can often be dramatically changed with gate contacts. This ability to drive a material far from equilibrium using external controls permits the amplification and switching behavior of transistors, as well as a variety of other nonlinear properties. For transistors based on charge motion, such as field-effect transistors, the typical modification of equilibrium achieved with the gate contact is the back-and-forth change of the material's conductance between the insulating and the metallic regime. For spin-based devices, it will be the controllable and reversible change of a spin-dependent or magnetic property.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

The first demonstration that the fundamental magnetic properties of a ferromagnetic semiconductor could be manipulated with an external contact was the demonstration of a voltage dependence of the Curie temperature in the ferromagnetic semiconductor InMnAs (Ohno *et al*., 2000). Since then an electric field has been shown to modify the coercive field of InMnAs (Chiba, Yamanouchi, Matsukura and Ohno, 2003) and as a result permit magnetization reversal. These demonstrations rely on the unusual nature of ferromagnetism in these materials. In order to modify the magnetic properties of these materials with an electric field, a sufficient number of carriers must be removable from the material with a modest-sized voltage, and the ferromagnetic state must depend on the density of these carriers. The requirement of carriers that mediate the magnetism suggests magnetic insulators would be poor candidates for gate control of magnetism. Magnetic metals are also poor candidates, for the density of carriers in a typical metal is orders of magnitude higher than in ferromagnetic semiconductors, and therefore it is not possible to remove enough carriers with a modest voltage to significantly modify the magnetic properties of a metal. Thus electrically switchable magnets, and the potential applications of such materials (e.g., electrically switchable magneto-optical elements or voltage-tunable sources of spin-polarized current) are likely restricted to devices made from ferromagnetic semiconductors.

The spin-dependent properties of carriers moving through nonmagnetic semiconductors can also be modified by the application of electric fields. Even though there is no equilibrium magnetization in these materials, the orbital properties of a specific electronic state are entangled with the spin properties of that state through the spin-orbit interaction. Semiconductors with inversion-symmetric crystal structures (such as silicon, germanium, and diamond) have doubly degenerate electronic states for all crystal momenta, but owing to the

spin-orbit interaction, the wave functions cannot be factored into a spin component multiplying an orbital component. This entanglement of spin and orbit leads to transport-dependent spin dynamics, including relaxation of spin-polarized distributions of carriers toward an equilibrium unpolarized state. For semiconductors with inversion-asymmetric crystal structures (such as gallium arsenide, zinc selenide, and other materials with zincblende or wurtzite crystal structures), the effect of the spin-orbit interaction is even more pronounced, leading to momentum-dependent spin splittings of the electronic states throughout the zone. An applied external electric field provides an additional inversion-asymmetric contribution to the overall crystal potential, and thus introduces a nonzero spin splitting into the electronic states of an inversion-symmetric material or modifies the spin splittings of an inversion-asymmetric material.

A seminal proposal (Datta and Das, 1990) described this mechanism for electric-field manipulation of the spin orientation of electrons moving through a high-mobility semiconductor channel. Since then many other manipulation proposals and device configurations have been discussed in the literature. These include both the use of electric fields to change the electronic structure of a region of the device (modifying the spin splittings of moving electrons) and the use of electric fields to change the average velocity of carriers which thus experience different average electronic structures (Koga, Nitta, Takayanagi and Datta, 2002). Some recent transistor suggestions have focused on simply modifying the spin relaxation time of carriers within a nonmagnetic semiconductor as a way of achieving gain (Hall *et al*., 2003b). Electric-field manipulation of the spin relaxation time has been demonstrated in GaAs/AlGaAs and InAs/AlSb quantum wells. On the basis of these observations and theoretical estimates of the fundamental limits of transistor performance (both for charge-based and spin-based devices) it has been suggested that spin-based transistor devices have superior fundamental performance limits than charge-based devices (Hall and Flatté, 2006).

The final category of devices to be considered here are those in which the electric fields, rather than controlling the properties of a single layer (magnetic or nonmagnetic), are used to control the relative potentials of two elements of the device. This type of control is commonly used in charge-based electronics, such as changing the relative potential of the p and n regions of a diode. These adjustments are then used to change the carrier transport through the device as a whole. When the elements of the structure are magnetic, then the magnetic properties of the current can be adjusted in addition to the total current, or the device functionality itself can be manipulated. One example of this type of device is a ferromagnetic semiconductor with 100% or nearly 100% spin-polarized carriers. A domain wall in such a material behaves similar to a p−n diode, but can be removed if desired to replace a nonlinear circuit element with a linear one (Flatté and Vignale, 2001).

2 GATE-CONTROLLED MAGNETS AND SEMICONDUCTOR SPINTRONIC DEVICES

2.1 Gate control of the properties of carrier-mediated ferromagnetic semiconductors

The fundamental physical properties of carrier-mediated ferromagnetic semiconductors differ significantly from those of magnetic insulators or magnetic metals and provide clues to the potential applications of such materials when they become available at and above room temperature. Magnetic semiconductors of this type, such as InMnAs (Munekata *et al*., 1989) and GaMnAs (Ohno *et al*., 1996) are grown by adding both magnetic ions and carriers to an initially nonmagnetic, insulating semiconductor. If only magnetic ions are added to a nonmagnetic semiconductor, such as in the case of Mn substituted for the group-II atom in a II−VI semiconductor such as ZnSe, then these ions are very weakly coupled and do not establish ferromagnetic order. This situation is shown in Figure 1. Although these materials are not ferromagnetic, their magnetic response can be very unusual. When the magnetic ion Mn replaces the group-III atom in a III−V semiconductor, such as InAs or GaAs, then the different valence of Mn provides an additional hole for each substitutional Mn. At low concentrations, each hole is bound to a substitutional Mn in an acceptor state with a radius of ∼1 nm, as shown in Figure 1. Shown in Figure 2 is a scanning tunnelling microscope (STM) measurement of the acceptor state associated with Mn when substituted in GaAs. The state itself is highly anisotropic due to the breaking of spherical symmetry by the cubic lattice of GaAs.

Although the hole would bind to the Mn location simply because of the attractive Coulomb potential from the effective negative charge of the Mn site, the acceptor level is much more strongly bound than would be expected for a shallow level. This additional binding originates from p−d hybridization, the coupling of the p-like valence states of GaAs with the core electronic d-like states of the Mn ion. As this coupling is highly spin-selective, the bound acceptor state is nearly 100% spin polarized, with the hole spin direction oriented antiparallel to the $S = 5/2$ core spin of the Mn ion. At the valence band edge the holes are members of a $J_h = 3/2$ multiplet, and thus the ground state of the combined core-spin-valence-hole Mn complex is $J = 1$.

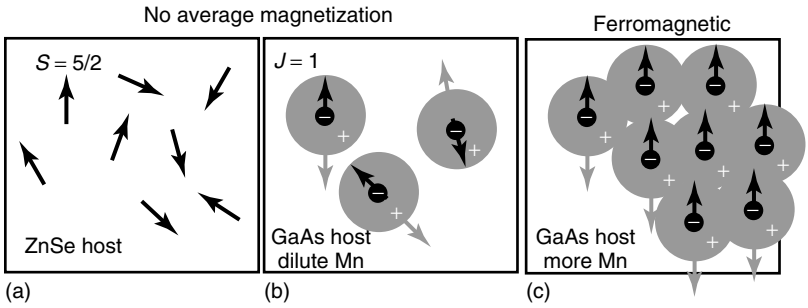

Figure 1. (a) When magnetic ions are placed in a nonmagnetic semiconductor without additional carriers the spins are very weakly coupled and not ferromagnetic. (b) Magnetic ions with bound holes placed in a nonmagnetic semiconductor are weakly coupled when at very dilute concentrations. (c) When the density of magnetic ions with bound holes is high enough, the carriers overlap, coupling the magnetic ions and producing ferromagnetism.

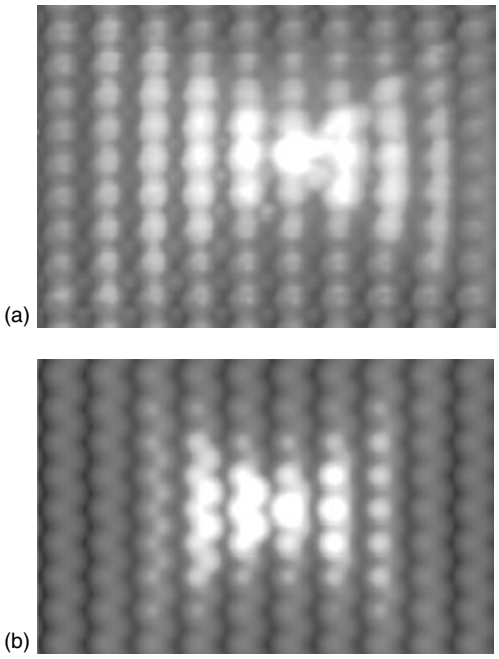

Figure 2. (a) STM image of neutral Mn. Big and small round features correspond to As and Ga related surface states, respectively. Mn is located in the fifth subsurface atomic layer; (b) simulated image of the Mn situated in the fifth subsurface atomic layer. (Reprinted with permission Yakunin *et al*., copyright 2004, American Physical Society.)

These properties of the ground state have been confirmed by electron-spin-resonance measurements on individual substitutional Mn ions (Schneider, Kaufmann, Wilkening and Baeumler, 1987).

When a sufficient density of Mn has been added these acceptor states overlap. If the spin orientations of the holes on two neighboring Mn are parallel then each hole can delocalize into a molecular state around both Mn. If, however, the spin orientations are antiparallel then the two acceptor states cannot hybridize with each other and each hole must remain localized around its own Mn. As the holes are more delocalized for parallel Mn alignment, and thus have lower energy, the ferromagnetic configuration is energetically favored. The energy splittings between these molecular states are observable with scanning tunneling spectroscopy and confirm the ferromagnetic alignment between neighboring Mn (Kitchen *et al*., 2006). As the acceptor state itself, seen in Figure 2, is spatially anisotropic, it is not surprising that the Mn–Mn coupling mediated by the bound holes is also spatially anisotropic. The consequence of this carrier-mediated coupling is a ferromagnetic state when the Mn doping density is sufficiently high (as shown in Figure 1).

Impressive quantitative calculations of the properties of ferromagnetic GaMnAs and other Mn-doped III–V ferromagnetic semiconductors have been achieved using a highly simplified picture of the electronic structure in Figure 1. In the 'mean-field' approach (Dietl, Ohno and Matsukura, 2001; Abolfath, Jungwirth, Brum and MacDonald, 2001; MacDonald, Schiffer and Samarth, 2005), the effective spin-dependent potential of the individual Mn ions is smeared out to a uniform spin-dependent potential throughout the solid. The hole density is also smeared out to a uniform value and the polarization of the Mn ions and the holes is determined self-consistently given the hole–Mn–ion interaction energy. This mean-field approach has successfully described the conductivity of GaMnAs, the magnetic anisotropy and magnetoelastic constants (Masmanidis *et al*., 2005), the dependence of the Curie temperature on doping and strain, and some of the chemical trends of other magnetic semiconducting materials. Limitations include predictions of room-temperature ferromagnetism in the semiconductors GaMnN and ZnMnO – predictions that have yet to be convincingly demonstrated.

Figure 1 also suggests how reducing the density of holes can reduce the Curie temperature of such a magnetic semiconductor. As the coupling between neighboring Mn core spins is mediated by the carriers, if there are fewer carriers the coupling will be weaker. The density of Mn required

to achieve the ferromagnetic state is only around 1% (with the largest Curie temperatures achieved for doping densities >5%). This means that only one hole for every 10–100 unit cells must be removed to fully deplete the material of carriers (and the Curie temperature can be observably modified even if only a small fraction of the carriers present have been removed). This behavior is possible because the host material for the magnetic ions is a nonmagnetic semiconductor. If the host material were a nonmagnetic insulator rather than a semiconductor any carriers would be strongly bound to the magnetic atoms inserted into the lattice. Thus the overlap with nearby spins would be of far shorter range, and ferromagnetism would not be achievable via carrier mediation until magnetic atoms were placed on a much larger fraction of lattice sites than required for these ferromagnetic semiconductors. If the host were a nonmagnetic metal then the density of carriers present at the start (typically of order one per unit cell) would be much larger than the density in these magnetic semiconductors, precluding the possibility of gating the magnetism. Carrier-mediated ferromagnetism itself would be less effective, for the sign of the spin–spin interaction mediated by a dense sea of carriers would oscillate rapidly in space (Ruderman–Kittel–Kasuya–Yosida coupling) owing to the Fermi surface structure. As a result, the behavior of a dilute alloy of magnetic atoms in a nonmagnetic host would be characterized by varying magnitudes and signs of spin–spin coupling, which tends to produce a spin glass rather than a ferromagnet.

2.2 Switchable Faraday isolators

Potential applications of gateable ferromagnets include switchable magneto-optical elements and voltage-tunable sources of highly spin-polarized current. One popular example of a magneto-optical element is the Faraday isolator, shown schematically in Figure 3. This device, commonly used to prevent feedback into laser cavities, provides one-way transmission of light. A one-way mirror violates time-reversal invariance, so a magnetic element is required to implement the device. In a magnetic material, the index of refraction differs for left and right circularly polarized light, an effect called *magnetic circular dichroism*. In the configuration of Figure 3, light that is linearly polarized passes through a Faraday rotator. A linearly polarized light beam can be decomposed into a coherent sum of a left and right circularly polarized beam. The index difference for these two components in the Faraday rotator generates a phase difference between the two that results in a rotation of the linear polarization direction for the beam as it passes through the material. In the schematic, the magnetization and length of the material is chosen so the beam rotates 45° counterclockwise. That beam can then pass through another linear polarizer mounted at the other end of the device and oriented at 45° to the initial polarizer. If light enters from the far end, however, it is filtered by the linear polarizer to a 45° polarization and is rotated an additional 45° while passing in the other direction through the Faraday rotator. As the sense of rotation is the same for light traveling in either direction through the Faraday rotator, when light enters from the far side it is rotated into a 90° oriented beam that cannot pass through the original linear polarizer. For communication wavelengths the material commonly used is yttrium iron garnet (YIG), which provides a large Faraday rotation and low optical loss. Use of a switchable ferromagnet would permit the one-directional transmission to be turned on or off, or the direction of the allowed transmission to be changed dynamically. Such magnetically switchable mirrors may find applications in high-speed switching and in high-speed displays.

2.3 Voltage-tunable sources of spin-polarized current

As the spin polarization of a carrier-mediated ferromagnetic semiconductor depends sensitively on the carrier density, applying a voltage to deplete the carriers will also modify the carrier spin polarization. This produces a voltage-tunable source of spin-polarized carriers. The spin polarization of this current, however, can be amplified by placing this ferromagnetic semiconductor in a transistor-like structure called a *magnetic bipolar transistor* (Flatté, Yu, Johnston-Halperin and Awschalom, 2003).

Shown in Figure 4 is a schematic of an $n-p_{\uparrow}-n$ transistor structure, consisting of an emitter and collector that are nonmagnetic n-doped semiconductors and a base that is a p-doped ferromagnetic semiconductor. In this structure, three general types of spin-selective processes can potentially cause minority electrons injected from the nonmagnetic n-doped emitter into the p-doped base to become spin polarized before passing into the collector. The first is a dramatic spin-filtering effect on carriers passing from the emitter to the $p_{\uparrow}$ base, the second is spin-selective conduction electron-spin flipping within the $p_{\uparrow}$ region, and the third is spin-selective recombination within the $p_{\uparrow}$ region. The result is a large current of highly spin-polarized electrons into the nonmagnetic collector of the device. This spin-polarized current can be controlled by any scheme that controls the orientation or magnitude of the base magnetization.

The spin-filtering effect originates from the spin splitting of the minority (conduction electron) band edges in the $p_{\uparrow}$ base (shown in Figure 4). Estimates of the spin splitting of the valence band in a p-doped magnetic semiconductor, such as GaMnAs, range from 20–100 meV. The conduction band

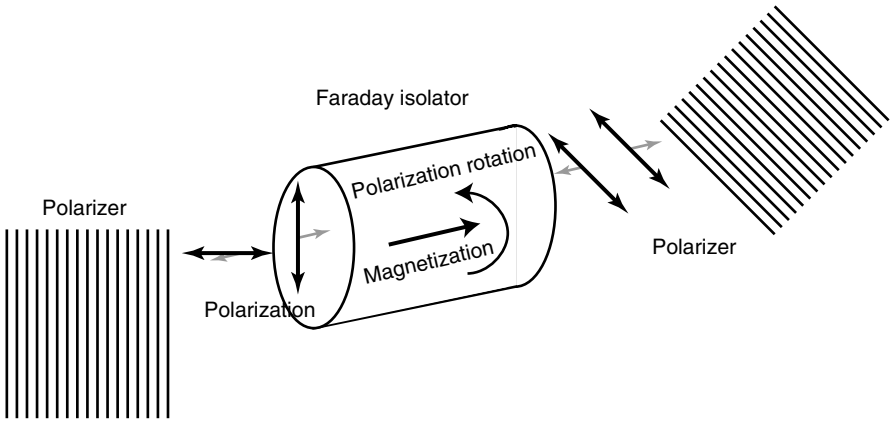

Figure 3. Schematic of a Faraday isolator. The breaking of time-reversal invariance for light propagation through the Faraday rotator leads, in combination with polarizers, to one-way transmission of light. Magnetic semiconductors may permit switchable Faraday isolators.

is split as well (Myers *et al*., 2005) through hybridization with the valence band and the d-levels, although by a smaller energy (S_c). The influence of the conduction band spin splitting on this proposed device is quite dramatic even for small splittings, for the equilibrium spin polarization of minority carriers in the base,

$$\frac{n_{\mathrm{B}\downarrow 0} - n_{\mathrm{B}\uparrow 0}}{n_{\mathrm{B}\downarrow 0} + n_{\mathrm{B}\uparrow 0}} = \tanh(S_c/2k_{\mathrm{B}}T) \tag{1}$$

where $n_{\mathrm{B}s0}$ is the equilibrium density of spin s conduction electrons in the base. When the device is biased the Shockley approximations fix the minority carrier quasichemical potential on the emitter side of the base equal to the chemical potential in the emitter (Figure 4). In an ordinary transistor this gives rise to the exponential dependence of the base's minority carrier density on the emitter–base voltage, V_{EB}. For a magnetic base, the enhanced minority carrier densities $n_{\mathrm{B}s}$ injected from the emitter will likewise increase exponentially, and retain the spin polarization of equation (1),

$$\frac{n_{\mathrm{B}\downarrow}}{n_{\mathrm{B}\uparrow}} = \frac{n_{\mathrm{B}\downarrow 0}}{n_{\mathrm{B}\uparrow 0}} \tag{2}$$

If the band alignment is as shown in Figure 4 then $n_{\mathrm{B}\downarrow} > n_{\mathrm{B}\uparrow}$, however, the other case is straightforward. The degree of spin polarization is considerably more dramatic than that expected for tunneling through a spin-split barrier (Moodera, Hao, Gibson and Meservey, 1988; Hao, Moodera and Meservey, 1990) and occurs in any base region thick enough to eliminate tunneling from emitter to collector.

A related structure, the spin-valve transistor (Monsma, Lodder, Popma and Dieny, 1995; Jansen, 2003; van Dijken, Jiang and Parkin, 2003), places a metallic spin valve (Ziese and Thornton, 2001) in the base region of a silicon transistor. Large variations in the collector current were found in such a device; however, in the spin-valve transistor the collector current is very small compared to the emitter and base currents. The magnetic bipolar transistor, however, potentially has a collector current that greatly exceeds the base current, yielding a gain much larger than one.

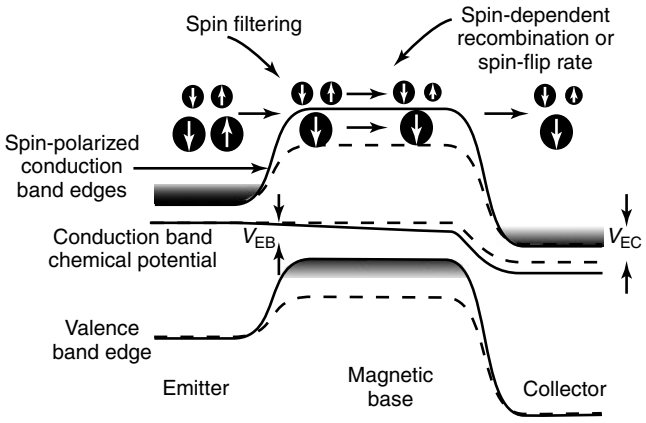

Figure 4. $\mathrm{n}-\mathrm{p}_{\uparrow}-\mathrm{n}$ transistor. Thermally excited unpolarized electrons in the emitter are filtered at the emitter–base interface and can be further polarized through spin relaxation or carrier recombination in the base. The spin-split conduction and valence band edges are shown in the magnetic base, as well as the conduction band quasichemical potential. Dashed (solid) lines are for spin-down (spin-up). Occupied states (electron or hole) are indicated with shading. (Reprinted with permission M.E. Flatte *et al*., copyright 2003, American Institute of Physics.)

The unusual device functionalities suggested by electrically tunable ferromagnetic semiconductors have yet to become practical for commercial devices. Limitations include the Curie temperatures of carrier-mediated ferromagnets (which remain far below room temperature at this time) and the material quality of the known ferromagnetic semiconductors. Increases in the highest Curie temperatures achieved for true carrier-mediated ferromagnets over the past

several years suggest that room-temperature carrier-mediated ferromagnets may be possible. Even if those are demonstrated, however, there are additional characteristics that must be improved before such materials could be used in the devices described in the preceding text. For Faraday isolators the optical loss must be small compared to the rotation angle, and current ferromagnetic semiconductor tend to have very poor optical properties, characterized by high optical losses at all wavelengths. The electric fields required to modify the magnetic properties of gate-tunable devices should be as small as possible; now the voltages required to deplete enough carriers to change the Curie temperature by as little as a single degree are much larger than practical for high-speed integrated devices.

3 CONTROL OF SPIN RELAXATION IN NONMAGNETIC SEMICONDUCTORS

Semiconductor spintronic devices may not require magnetic materials. It has already been established experimentally that the flow of current through nonmagnetic semiconductors can produce spin-polarized distributions, either uniformly in space (Kato, Myers, Gossard and Awschalom, 2004a; Silov *et al*., 2004) or by spatially separating a moving, initially unpolarized distribution into two oppositely polarized distributions (Kato, Myers, Gossard and Awschalom, 2004c; Wunderlich, Kaestner, Sinova and Jungwirth, 2005; Sih *et al*., 2005). Both effects, current-induced spin polarization and the spin-Hall effect, have recently been demonstrated at room temperature (Stern *et al*., 2006). The spin-orbit interaction, which couples the motion of the electrons to the spin dynamics, plays an important role in these phenomena (D'yakonov and Perel', 1971; Levitov, Nazarov and Éliashberg, 1985; Edelstein, 1990; Hirsch, 1999; Murakami, Nagaosa and Zhang, 2003; Sinova *et al*., 2004). See also **Theory of Spin Hall Effects in Semiconductors, Volume 5** in this volume will address these topics in more detail.

Once an initial nonequilibrium spin polarization has been generated, then additional methods can be used to manipulate the population's spin orientation. One method is interfering one population with another (Kato, Myers, Gossard and Awschalom, 2005). As the spin coherence lengths in semiconductors are exceptionally long (Kikkawa and Awschalom, 1999; Sogawa *et al*., 2001) and can exceed 100 μm in some materials, manipulations that rely on spin population interference can work over much longer length scales than possible for devices relying on orbital coherence. Distributions can also be moved into regions with different spin lifetimes to either store or destroy spin coherence (Malajovich, Berry, Samarth and Awschalom, 2001).

In addition to these effects, the simple act of transporting the spin population through a nonmagnetic semiconductor with spin-orbit interaction can cause the spin orientation to precess, even without applied magnetic fields. When electrons move through a crystal, the electric fields associated with the crystal potential are relativistically transformed into effective magnetic fields acting in the rest frame of the electrons. These effective magnetic fields depend on the direction of electron motion through the crystal, and thus will cause the spin orientation to precess in a path-dependent way (Kato, Myers, Gossard and Awschalom, 2004b; Crooker and Smith, 2005; Crooker *et al*., 2005).

3.1 Electric-field control of internal effective magnetic fields

As the internal effective magnetic fields arise from a relativistic transformation of the crystal's electric fields into the rest frame of a moving electron, those magnetic fields can be controlled in any way that changes the crystal's electric fields in the laboratory frame. A simple way to do this is to apply a uniform electric field. The tunable effective magnetic field experienced by moving electrons that arises from this electric field provides additional strategies to manipulate a spin population. In the seminal work of Datta and Das (1990), the spin orientation of carriers moving ballistically from source to drain in a transistor geometry is controlled by such an effective magnetic field induced with a uniform electric field applied to the crystal. This 'Rashba' field **B** (Rashba, 1960; Bychkov and Rashba, 1984) has the form

$$\mathbf{B} = \alpha\ \mathbf{E} \times \mathbf{k} \tag{3}$$

where **E** is an effective electric field, **k** is the carrier's crystal momentum, and α depends on the strength of the spin-orbit interaction in the material. Even in the absence of a true applied electric field, the presence of inversion-symmetry breaking in a structure ('structural inversion asymmetry') can produce an effective electric field and a resulting Rashba field. For an electric field generated by a gate and pointing parallel to z, the Rashba field will point in the xy plane perpendicular to **k**. When carriers move ballistically along x from source to drain in a transistor geometry, for example in a quantum wire, all the carriers have the same **k**, and the Rashba field (parallel to y) is the same for all carriers. In more general situations in which carriers are distributed through momentum space, the spins of the individual carriers will precess relative to each other (in a phenomenon called *dephasing*), and the total spin polarization moving from source to drain will decay.

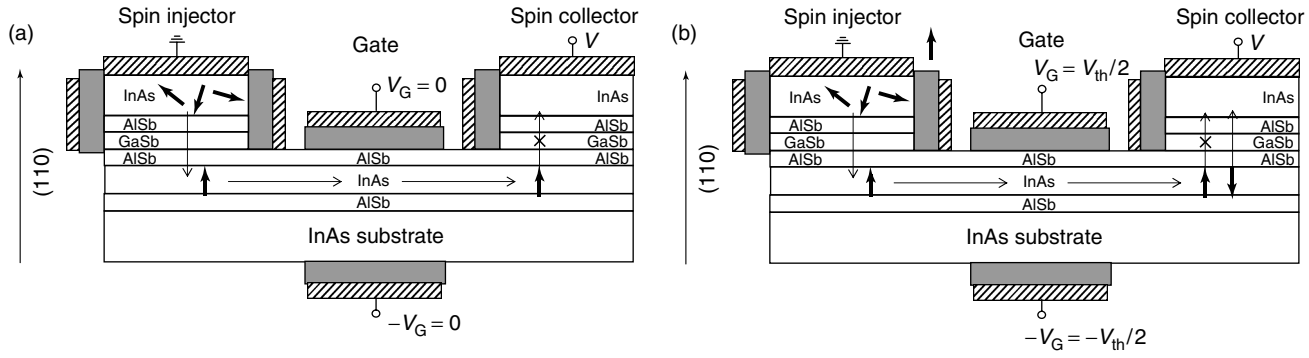

Figure 5. Schematic of the spin transistor of (Hall *et al*., 2003b) in (a) the 'off' and (b) the 'on' state. The spin injector (source) and collector (drain) are configured to select opposite spin polarizations. If the spin lifetimes are very long (gate voltage off) in the channel then no current will flow from source to drain. If the spin lifetimes are short (gate voltage on), then current can flow easily from source to drain. (Reprinted with permission K. Hall *et al*., copyright 2003, American Institute of Physics.)

If carriers move through a material by diffusion, rather than by ballistic transport, the varying momenta of the carriers leads to dephasing of the carriers relative to each other and an overall loss of spin polarization. Through the choice of a clever geometry, balancing the gate electric field with the internal electric fields from a crystal structure (Schliemann, Egues and Loss, 2003), partially coherent spin manipulation is possible even for diffusing carriers. In current structures near room temperature, however, the propagating carriers lose their spin polarization in less than 1 ns (Lau and Flatté, 2005). Thus an alternate approach for diffusive carriers is desirable.

A simpler design relies on the controllable decay of spin polarization rather than its reorientation. In zinc-blende semiconductors, the spin lifetime originates from differing effective magnetic fields for different carriers (D'yakonov and Perel', 1972; Dresselhaus, 1955). Zinc-blende quantum wells grown in the (110) direction are special, for the spin lifetime for spins oriented parallel to the (110) direction is very long (D'yakonov and Kachorovskii, 1986; Winkler, 2004; Ohno *et al*., 1999a; Hall *et al*., 2003a). If an electric field is applied in the (110) direction, however, a Rashba field is generated perpendicular to (110), causing the spin lifetimes to shorten (Lau and Flatté, 2002) by several orders of magnitude. Reductions of a factor of 10 in the spin lifetime in a GaAs/AlGaAs quantum well (Karimov *et al*., 2003) and of a factor of 4 in the spin lifetime in an InAs/AlSb quantum well (Hall *et al*., 2005) have been observed experimentally.

3.2 Spin transistor action in a nonmagnetic semiconductor

This controllable spin lifetime forms the basis for transistor action in the device (Hall *et al*., 2003b) shown in Figure 5. Once polarized spins (to be specific, spin-up) have been injected into a channel, either from a magnetic material (Fiederling *et al*., 1999; Ohno *et al*., 1999b; Hanbicki *et al*., 2002; Adelmann *et al*., 2005) or using a nonmagnetic spin filter (Andrada e Silva and La Rocca, 1999; Voskoboynikov, Lin, Lee and Tretyak, 2000; Koga, Nitta, Takayanagi and Datta, 2002; Hall *et al*., 2003b), their motion through the device can be controlled according to whether they remain spin polarized or not (Hall *et al*., 2003b). If they remain spin polarized and the drain contact spin filter only accepts spin-down carriers, then current does not flow from source to drain. This is the situation (Figure 5a) when no electric field is applied using the gate contact. When an electric field is applied (Figure 5b) then the spin polarization decays rapidly in the channel. In this situation, current flows easily from source to drain. Hence, in this design, there is no moveable barrier between source and drain. The spin-dependent barriers in this device permit carriers of one spin orientation to pass while preventing those of the other spin polarization. The spin-dependent barriers are not raised or lowered. The switching is performed instead by changing the spin orientation in the channel.

Transistor action in a CMOS field effect transistor (FET), by contrast, requires raising and lowering a barrier whose height is set by the gate voltage. When the barrier is high the source–drain current cannot flow, whereas when it is low the source–drain current flows easily. For low standby power (LSTP) CMOS (Semiconductor Industry Association, 2003) the switchable range of the height of the barrier, V_{th}, must be at least 400 mV, corresponding to $16k_BT$, or a thermally excited current over the barrier in the 'off' state of 10^{-7} the 'on' current. Here k_B is Boltzmann's constant and T is the temperature. The gate capacitance of the CMOS FET, C_g, is proportional to the area of the region of the channel that

is blocked with this barrier. The power-delay product (twice the switching energy) is $C_g V_{th}^2$ and the switching time is proportional to C_g. If the gate capacitance is too low then the barrier becomes thin enough that carriers can tunnel through it and the leakage current rises above that expected from V_{th}, but if the capacitance is too high the switching time is long and the switching energy high.

Although the difference in 'on' and 'off' gate voltages for low standby power (LSTP) CMOS cannot be reduced below 400 mV for a 10^7 on–off current ratio at room temperature ($\sim$280 mV for a 10^5 on–off current ratio), the difference in 'on' and 'off' gate voltages for the spin transistor described in the preceding text can be much less. The source–drain current is proportional to the spin relaxation rate, so for a 10 ps spin lifetime in the 'on' state and a 10^5 on–off ratio the spin lifetime must be 1 µs in the off state (100 µs for a 10^7 on–off ratio). Spin lifetimes in excess of 150 ns have been observed experimentally in bulk GaAs (Kikkawa and Awschalom, 1998), so here the 1 µs value will be used. It only requires an average 1 meV spin splitting (associated with a random effective magnetic field direction) to cause a spin to relax within 1 ps. This spin splitting is not generated directly by the gate voltage, but is induced by the applied electric field and the spin-orbit interaction of the material as described by equation (3). For the 20 nm thick InAs quantum well of Hall *et al.*, 2003b the required electric field to reduce the spin lifetime to 10 ps at room temperature is 50 kV cm^{-1}. Thus, the threshold voltage will be 100 mV, a factor of 4 less. It can be reduced even further if a material with a larger spin-orbit interaction than InAs (such as InSb or an InAs/GaSb superlattice) is used instead.

The other quantity entering the dynamic power dissipation (power-delay product) is the gate capacitance, from

$$C_g = \epsilon_0 \epsilon_s \frac{A}{d} \tag{4}$$

where ϵ_0 is the dielectric permittivity of vacuum, ϵ_s the relative dielectric constant of the semiconductor, A the area of the gate, and d the thickness of the region the electric field is applied to. In CMOS the thickness of the oxide layer determines d, whereas for the spin transistor the quantum well thickness determines d. For a spin transistor based on InAs/AlSb with a gate of the same area as a CMOS gate the gate capacitance is a factor of 5 smaller (as the 20 nm thick quantum well is much thicker than the CMOS gate oxide). The threshold voltage and the gate capacitance indicates that the dynamic power dissipation would be a factor of 500 times smaller for the spin transistor than LSTP CMOS in 2018 (Hall and Flatté, 2006).

The other important form of power dissipation is the static power dissipation. In CMOS, the dominant source of static power dissipation is the source–drain leakage current. The target value for 2018 LSTP CMOS is 100 pA/µm^{-1}. In the spin transistor, the dominant source is the spin relaxation in the 'off' state. For the gate length target in 2018 LSTP CMOS of 10 nm, a quantum well doping of 2×10^{12} cm^{-2} and a 1 µs spin relaxation time, the leakage current for the spin transistor will be 16 pA/µm^{-1}, a factor of 6 smaller than for LSTP CMOS in 2018.

The switching speed is also an important metric and depends on the source–drain current in the 'on' state, the threshold voltage, and the gate capacitance. For a 10 ps 'on' spin relaxation time and the parameters above, the switching time will be 3 ps, 10 times longer than the target for 2018 LSTP CMOS. Increasing the carrier doping level in the quantum well reduces the switching time, although it also increases the static leakage current. The switching time can be reduced without increasing the leakage current if the spin transistor quantum well uses a material with a larger spin-orbit interaction, such as InSb or InAs/GaSb superlattices.

Direct comparisons are possible between spin transistor design performance and CMOS performance. These comparisons suggest that the static power dissipation and the dynamic power dissipation would be smaller for the spin transistor (Hall and Flatté, 2006). This improved performance originates from the lower threshold voltage and the lower gate capacitance of the spin transistor design. The switching speed of the design of Hall *et al.*, 2003b is slower than CMOS. It can be made faster if the InAs quantum well is replaced with a material that has a larger spin-orbit interaction.

Progress toward implementing a scalable side-gate structure that would permit spin injection from a nonmagnetic material has been achieved; a prototype of the side-gated structure has been demonstrated using fabrication techniques that are scalable to deep submicron scales, although the spin-switching properties have yet to be confirmed in that prototype (Moon *et al.*, 2004). Use of the (110) growth direction as described here reduces the effect of spin-orbit interaction on the spin lifetime in the 'off' state, for the spin lifetime for (110)-oriented spins should be very long. The rapid spin relaxation in the 'on' state is still retained for the (110) growth direction. Narrow-gap semiconductor materials are the subject of intense investigation for high-speed low-power integrated circuit applications, although the considerations that will determine whether they are competitive with other material systems (especially silicon CMOS) differ for spin-based devices relative to charge-based devices.

The spin transistor described here works through electric-field control of the decay of spin polarization, and hence could be considered an incoherent semiconductor spintronic device. Spin transistors also permit the manipulation of their output currents through reorienting the source and drain

magnetic layers (Hall *et al*., 2003b; Sugahara and Tanaka, 2004) in a fashion similar to spin valves (Ziese and Thornton, 2001). Other logical elements may be possible which depend on electrical control of the coherent propagation properties of spin in semiconductors, including the spatial period of spin precession originating from the Rashba field described in the preceding text. Such devices may be able to perform more complicated operations than a transistor or may provide an efficient method of implementing analog logic. The behavior of such devices, and comparisons with competing charge-based devices, is not as thoroughly explored as those of 'spin transistors' and offers fertile ground for future theoretical device physics research.

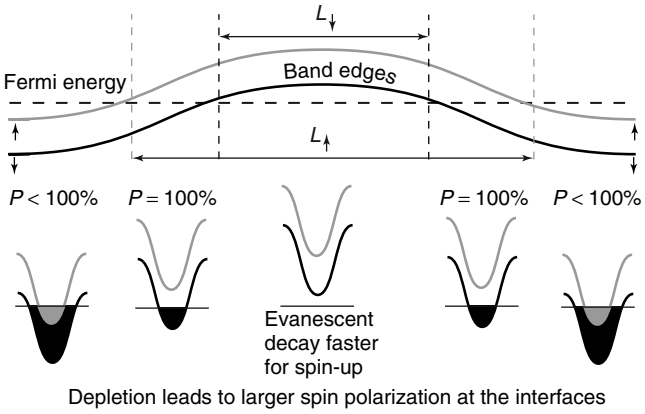

Figure 6. Schematic of the spin-split band edges of a carrier-mediated ferromagnetic semiconductor as the carrier density is varied from metallic to insulating and back to metallic. If the variation occurs over a length scale small compared to the range of the exchange interaction then the bands remain spin split even without carriers. Thus depleted ferromagnetic semiconductors can be natural half-metals.

4 NONLINEAR TRANSPORT IN MAGNETICALLY INHOMOGENEOUS STRUCTURES

The low carrier density of carrier-mediated ferromagnetic semiconductors, which permits electric-field control of magnetism, also suggests that unusual transport phenomena might occur near interfaces and edges. If the carrier density is very high, such as in magnetic metals, or the range of spin–spin interaction is short, such as in magnetic insulators, then bulk behavior is usually recovered within one atomic layer of the interface. Frequently the final atomic layer of a magnet is a 'magnetically dead' region, with much lower or negligible spin polarization, or very high levels of spin-flip scattering. In a tunnel-junction geometry, this magnetically dead region can dominate the transport, greatly reducing the apparent spin polarization of the magnetic material.

4.1 Depletion and spin polarization near the edge of a magnetic semiconductor

Ordinarily if there are no carriers in the carrier-mediated ferromagnet then the spin polarization of the region vanishes and the material ceases to be magnetic. However, the lower carrier density and the long-range spin–spin interaction in magnetic semiconductors (see Figure 1) suggest that the region of modified magnetic properties should extend a distance of order the radius of the acceptor state away from the interface. Over this region of $\sim 1-2$ nm there is a strong exchange interaction even though there are few or no carriers. The situation is shown schematically in Figure 6 for an electron-doped carrier-mediated ferromagnetic semiconductor, although the situation for a hole-doped material is very similar. If the length scale of the variation in carrier density is small compared to the range of the exchange interaction (this $\sim 1-2$ nm), then the spin splitting of the band edge should roughly remain constant through the region of carrier density change.

As shown in Figure 6, upon moving from a region with higher carrier density to one of lower carrier density it is possible that the remaining carriers would become much more highly spin polarized than they would be either in the bulk of the magnetic semiconductor or in a bulk material with the same carrier density as the depleted region near the edge. Thus, a 100% spin polarized or nearly 100% spin-polarized material might be achievable near the edge of an ordinary magnetic semiconductor whose carriers are polarized significantly less than 100%. If the carrier depletion is continued until all carriers have been depleted (of both spin polarizations), then the remaining spin splitting in the electronic structure can still affect the transport by modifying the evanescent decay of the wave functions differently for spin-up and spin-down carriers. As shown in Figure 6, the width of the effective depleted region of the electron gas for carriers oriented spin-up, $L_\uparrow$, is much wider than that for carriers oriented spin-down, $L_\downarrow$. The evanescent decay of spin-up wave functions should also be much more rapid than that of spin-down wave functions. As a result, the resistance of this interface region to the tunneling of spin-up carriers should be much larger than the tunneling resistance for spin-down carriers. A treatment of the interface behavior when the depletion length is shorter than the exchange interaction predicts tunneling magnetoresistances much larger than would be expected from the bulk spin polarization of the magnetic semiconductor. This effect was seen in GaMnAs nanoconstrictions (Rüster *et al*., 2003), for which 2000% magnetoresistances were observed even

though GaMnAs in bulk has a spin polarization closer to 85% (Braden *et al*., 2003).

4.2 Unipolar spin diodes and transistors

Although the very large magnetoresistance described in the preceding text is considerably greater than that seen in metallic systems, it remains a linear resistive property. Most of the interesting properties of semiconductor charge-based devices are nonlinear transport properties, which suggests examining the nonlinear transport properties associated with inhomogeneous magnetic materials for unusual behavior. One interesting situation, that will now be analyzed, is that of the transport properties of a domain wall between 100% spin-polarized ferromagnetic semiconductors.

The current–voltage characteristics of this domain wall can be simply understood through an analogy between unipolar ferromagnetic semiconductors and nonmagnetic bipolar materials. This analogy is best visualized in the relationship between transport through the 180° domain wall between 100% spin-polarized semiconductors, which will be referred to as a 'spin diode', and transport through the traditional p–n diode. Shown in Figure 7(a) are the band edges of the conduction and valence band for a traditional p–n diode in equilibrium. The quasi Fermi levels are shown as dashed lines. To assist in exploring the analogy with the spin diode, Figure 7(b) shows the energies of the elementary carriers in those bands: conduction electrons and valence holes. This unfamiliar diagram is obtained merely by noting that the energy of a hole in the valence band is the negative of the energy of the valence electron (relative to the chemical potential). Figure 7(b) more clearly illuminates the similarities with the band edges for the spin diode, which are shown in Figure 7(c). Just as for the p–n diode, in the unipolar spin diode the majority carriers on one side are the minority carriers on the other side.

A major difference, however, is that the two types of carriers in the p–n diode have opposite charge, whereas in the spin diode they have the same charge. One implication of this is that in the p–n diode the interface between the layers is a *charge* depletion layer, whereas in the spin diode the interface is a *spin* depletion layer. Another major difference resulting from the charges of the carriers is the way the carrier energies shift under bias.

In the p–n diode under forward bias, the barriers for both valence hole and conduction electron transport across the junction are reduced. As shown in Figure 7(d) and 7(e) this leads to an increase in the conduction electron current to the left-hand side and the valence hole current to the right-hand side. Because the carriers have opposite charge, both increases result in an increased charge current to the right-hand side. For the spin diode (Figure 7(f)), only the barrier for spin-up electrons moving to the left-hand side is reduced – the barrier for spin-down electrons moving to the right-hand side is increased. The charge current is thus directed to the right-hand side and the spin current to the left-hand side. Under reverse bias, the barriers for carrier transport are both increased in the p–n diode Figure 7(g) and 7(h), yielding rectification of the charge current. For the spin diode Figure 7(i), again one barrier is reduced and the other increased. Thus the charge current is not rectified but the spin current is. With analogous assumptions to the Shockley assumptions for an ideal diode, the charge current density J_q and the spin current density J_s depend on the voltage V according to:

$$J_q = 2qJ_o\sinh(qV/k_BT) \tag{5}$$

$$J_s = 2\hbar J_o\sinh^2(qV/2k_BT) \tag{6}$$

where $J_o = Dn_m/L_m$, q is the electron charge, $\hbar$ is the Planck's constant, D is the diffusion constant, n_m is the minority carrier density, and L_m is the minority spin diffusion length. The resulting spin polarization of the current is

$$P = (2qJ_s/\hbar J_q) = \tanh(qV/2k_BT) \tag{7}$$

Thus the spin polarization approaches unity as V gets large, and approaches 0 for small V. The relative directions of the charge and spin currents are shown on Figure 7 for the cases of forward and reverse bias.

For ease of use as components in integrated circuits, a magnetoelectronic device should allow for magnetic manipulation of the charge current gain – to achieve this, back-to-back spin diodes are required (shown in Figure 8). Analyzing this structure in a similar way to a bipolar nonmagnetic transistor, the collector current density is

$$\begin{aligned} I_C = &-\frac{qJ_o}{\sinh(W/L)} \\ &\times [(e^{-qV_{EB}/k_BT} - 1) - (e^{-qV_{CB}/k_BT} - 1)\cosh(W/L)] \\ &- qJ_o[e^{qV_{CB}/k_BT} - 1] \end{aligned} \tag{8}$$

and the emitter current is

$$\begin{aligned} I_E = &-\frac{qJ_o}{\sinh(W/L)} \\ &\times [(e^{-qV_{EB}/k_BT} - 1)\cosh(W/L) - (e^{-qV_{CB}/k_BT} - 1)] \\ &+ qJ_o[e^{qV_{EB}/k_BT} - 1] \end{aligned} \tag{9}$$

The base width is W, the voltage between emitter and base is $V_{BE} < 0$, and the voltage between collector and

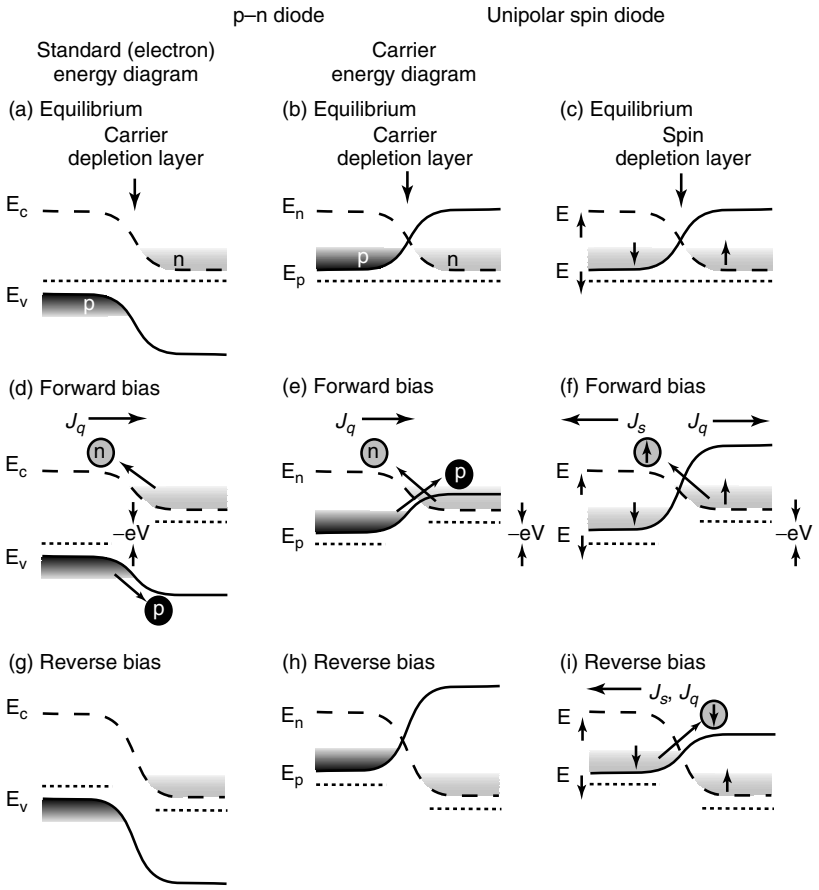

Figure 7. Standard and carrier energy diagrams for a traditional p–n diode versus unipolar spin diode under equilibrium conditions (a)–(c), forward bias (d–f), and reverse bias (g–i). (Reprinted with permission from M.E. Flatte & G. Vignale, copyright 2001, American Institute of Physics.)

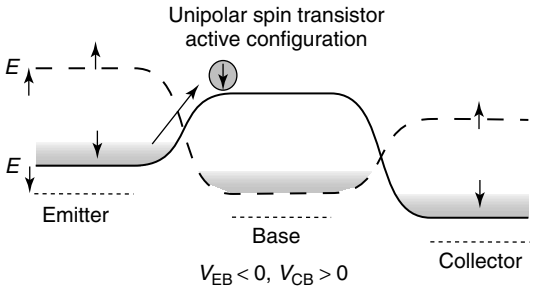

Figure 8. Carrier energy diagram for the unipolar spin transistor in the normal active configuration. (Reprinted with permission from M.E. Flatte & G. Vignale, copyright 2001, American Institute of Physics.)

base is $V_{CB} > 0$. The base current is $I_B = I_E - I_C$. When W/L is small, $I_B \ll I_C$, which is the desired situation for transistor operation (current gain $I_C/I_B \gg 1$). Leakage from the base to the collector (a process in this device similar to leakage from the base to the emitter in an ordinary bipolar transistor) can be suppressed (Flatté and Vignale, 2005) by making the collector spin splitting larger than that of the base or emitter (a similar approach to making a heterostructure bipolar transistor).

Thus it should be possible to program a logical circuit which behaves like a bipolar logical circuit using a uniformly doped unipolar magnetic material. The p-like regions correspond to regions with the magnetization pointing one way and the n-like regions correspond to region with the magnetization pointing in the opposite direction. Such logical circuits can include memory circuits, thus indicating that nonvolatile memory can be constructed as well.

Spin-flip of carriers moving through the domain wall acts like a recombination current in a bipolar device, and so should be reduced if at all possible. This can be done by making the domain wall thinner. Calculations of ballistic spin-preserving transport through domain walls, both with (Vignale and Flatté, 2002) and without (Deutsch, Vignale and Flatté, 2004) a bias applied to the spin diode, indicate that the transport can be predominately spin-preserving under reasonable conditions for transistor operation.

5 SUMMARY

The semiconductor spintronic devices described here function because of either the unique properties of carrier-mediated ferromagnetic semiconductors or the possibility of controlling the internal effective magnetic fields in nonmagnetic semiconductors. Many of the same characteristics that make semiconductors tremendously useful for ordinary charge transport, such as the ability to modify the electronic structure and carrier concentration with relatively weak electric fields, the intrinsic nonlinearities of transport in semiconductor systems, and the large length scales over which semiconductors return to equilibrium (compared with both metals and insulators), are essential to the subtle spin-dependent phenomena described here.

The single improvement in material properties that would be most helpful in the commercialization of these devices is the demonstration of a true carrier-mediated ferromagnetic semiconductor at a temperature exceeding room temperature. Ideally the carrier density in such a semiconductor would be relatively low, permitting modification of the Curie temperature with a small electric field. For the magneto-optical elements described here, such as Faraday isolators, such room temperature carrier-mediated ferromagnetic semiconductors would also need to generate large Faraday rotation angles with relatively small optical losses. For nonmagnetic spin transistors, the demonstration of extremely efficient spin injection (the injection of distributions that are nearly 100% spin polarized) is the next significant technological step. For unipolar and bipolar spin diodes and transistors, the key roadblock is to reduce the carrier density of the ferromagnetic semiconductors to the point where a voltage can be sustained across the depletion layer.

Theory of Spin Hall Effects in Semiconductors

Hans-Andreas Engel, Emmanuel I. Rashba and Bertrand I. Halperin
Harvard University, Cambridge, MA, USA

1 INTRODUCTION

In the simplest version of a spin Hall effect, an electrical current passes through a sample with spin-orbit interaction, and induces a spin polarization near the lateral edges, with opposite polarization at opposing edges (D'yakonov and Perel', 1971). This effect does not require an external magnetic field or magnetic order in the equilibrium state before the current is applied. If conductors are connected to the lateral edges, spin currents can be injected into them. Electrical current in a sample can also produce a bulk spin polarization, far from the edges, which is not generally classified *per se* as a spin Hall effect, though it is intimately related and is an important ingredient of spin Hall calculations.

Spin Hall effects have received a great deal of theoretical attention recently, in part because the subject includes ingredients of spintronics, electrical generation, transport, and control of nonequilibrium spin populations, and also because analysis has shown that the problem has remarkable subtlety. Theoretical efforts were also fueled by recent experimental observations of these effects.

In the following we consider semiconductors, where the various mechanisms of spin-orbit coupling are well known and can be roughly classified into two categories. First, the extrinsic mechanism is only present in the vicinity of impurities and leads to spin-dependent scattering, including Mott skew scattering. Second, the intrinsic spin-orbit coupling remains finite away from impurities and can be understood as a (often spatially homogeneous) spin-orbit field inherent in the band structure. Furthermore, the spin-orbit couplings are strongly symmetry dependent and are therefore different for electron and for hole carriers, and are different for two- and three-dimensional systems. Thus, the microscopic processes involved in generating a spin Hall effect can depend critically on such system properties. Initially, there was hope that spin-transport theory can be formulated in terms of universal spin currents that would simplify our understanding; however, it turned out that there is no such universality. As there is no unique description of the spin Hall effect, we should rather refer to it as a set of spin Hall effects.

There is already a vast amount of theoretical literature available on spin Hall effects and on the related spin currents. It is beyond the scope of this chapter to provide a historical overview or to give an explanation of all the theoretical techniques used. We rather provide an overview of the various mechanisms, explain them using intuitive and qualitative physical pictures, and give a summary of some key theoretical descriptions and results.

In contrast, the number of experiments on spin Hall effects is small and an overview is straightforward. In the experiment by Kato, Myers, Gossard and Awschalom (2004b),

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

electrical currents in three-dimensional n-GaAs layers (2 μm thick) induced a spin Hall effect, which was optically detected via Kerr microscopy. Measurements in strained samples showed little dependence of the effect on the crystal orientation and it was concluded that the extrinsic mechanism proposed by D'yakonov and Perel' (1971) was causing the spin Hall effect (Kato, Myers, Gossard and Awschalom, 2004b). Indeed, the experimental data can be described with reasonable accuracy by the extrinsic mechanism in a model based on scattering by screened Coulomb impurities (Engel, Halperin and Rashba, 2005), as well as one based on short-range scatterers (Tse and Das Sarma, 2006a) (see Section 4.3). Similar experiments in ZnSe (Stern *et al*., 2006) were also in agreement with theory, and a spin Hall effect was observed at room temperature. In another experiment, Wunderlich, Kaestner, Sinova and Jungwirth (2005) observed a spin Hall effect in two-dimensional layers of p-GaAs by detecting the polarization of recombination radiation at the edges of the sample. They ascribed this effect to the intrinsic mechanism, which is consistent with the magnitude of the observation (Schliemann and Loss, 2005; Nomura *et al*., 2005). Furthermore, in measurements on a two-dimensional electron system in an AlGaAs quantum well, a spin Hall effect was also observed and ascribed to the extrinsic mechanism (Sih *et al*., 2005). Finally, Valenzuela and Tinkham (2006) observed a reciprocal spin Hall effect in Al, where a spin current induced a transverse voltage via the extrinsic mechanism (Hirsch, 1999).

In addition to theoretical works in the traditional sense, there is also a large amount of numerical simulations on concrete realizations of disordered systems, for example, on a finite lattice. It has generally been difficult to make direct comparisons between numerical simulations and theoretical predictions, in part because theoretical works usually assume that the spin-orbit splittings are much less than the Fermi energy, whereas simulations tend to employ larger spin-orbit splittings in order to obtain numerically significant results. See, for example, (Ando and Tamura, 1992; Sheng, Sheng and Ting, 2005; Nikolić, Zârbo and Souma, 2005; Li, Hu and Shen, 2005).

In Section 2 below, we review the mechanisms for spin-orbit coupling in the semiconductors of interest, and we discuss forms of the effective Hamiltonians that describe the carriers in various situations. In Section 3, we see how the various effective Hamiltonians can influence spin transport and accumulation. We discuss spin precession, produced by the intrinsic spin-orbit coupling, as well as skew scattering and the so-called side-jump effect, resulting from the extrinsic spin-orbit coupling. We introduce Boltzmann-type kinetic equations which can describe spin transport and accumulation in various situations, and we discuss the simpler spin and charge diffusion equations which can be typically used in situations where the spin-relaxation rate is much slower than momentum relaxation.

In Section 4, we discuss explicitly the spin polarization and spin transport arising from an electrical current in a semiconductor with spin-orbit coupling. We introduce the notion of a spin current and the spin Hall conductivity, and we discuss results that have been obtained for these quantities in various situations. We also discuss a relation between the spin Hall conductivity and the so-called anomalous Hall effect that can result from spin-orbit coupling in a ferromagnet or in semiconductor with a spin polarization induced by an external magnetic field.

Spin currents are not directly observed in experiments, however. If spin-relaxation rates are slow, one may expect that spin currents with a nonzero divergence can lead to observable local spin polarizations, in which relaxation of excess spin balances the accumulation of spin that is transported into a region by the spin current. Furthermore, boundary effects may be important and nontrivial; in the presence of an electric current, spin polarization may be generated directly at a sample boundary. These issues are discussed in Section 4.5. We also briefly discuss mesoscopic systems, where all parts of the sample are close to a boundary.

A different type of spin Hall effect, associated with edge states, has been predicted to occur in certain systems that are insulating in the bulk, where the topology of the band structure has been altered due to spin-orbit coupling. In Section 5, we discuss this concept, along with the possibility that such effects may occur and be observable in a number of materials.

2 SPIN-ORBIT COUPLING IN SEMICONDUCTORS

For a nonrelativistic electron in vacuum, the Dirac equation can be reduced to the Pauli equation, describing a two-component spinor and containing the Zeeman term. The Pauli equation also contains relativistic corrections – including the spin-orbit coupling

$$H_{\mathrm{SO,\,vac}} = \lambda_{\mathrm{vac}}\, \boldsymbol{\sigma} \cdot (\mathbf{k} \times \nabla \tilde{V}) \tag{1}$$

Here, we used $\lambda_{\mathrm{vac}} = -\hbar^2/4m_0^2c^2 \approx -3.7 \times 10^{-6}$ Å^2, vacuum electron mass m_0, velocity of light c, and $\mathbf{k} = \mathbf{p}/\hbar$. In a semiconductor, we split the total potential $\tilde{V} = V_{\mathrm{cr}} + V$ into the periodic crystal potential V_{cr} and an aperiodic part V, which contains the potential due to impurities, confinement, boundaries, and external electrical field. One then tries to eliminate the crystal potential as much as possible and to

describe the charge carriers in terms of the band structure. The simplest systems of this sort can be exemplified by electrons in cubic direct-gap semiconductors. Then, the minimum of the energy spectrum is usually near the center of the Brillouin zone, and the twofold Kramers degeneracy is the only degeneracy of the spectrum at $k = 0$. It follows from symmetry arguments that for slow electrons in such crystals, and for slow carriers (electrons and holes) in high symmetry two-dimensional systems, the effective single-particle Hamiltonian is

$$H_{\text{eff}} = \epsilon_k + V + H_{\text{int}} + H_{\text{ext}} \tag{2}$$

$$H_{\text{int}} = -\frac{1}{2}\,\mathbf{b}(\mathbf{k}) \cdot \boldsymbol{\sigma} \tag{3}$$

$$H_{\text{ext}} = \lambda\, \boldsymbol{\sigma} \cdot (\mathbf{k} \times \nabla V) \tag{4}$$

where $\mathbf{k}$ is the crystal wave vector relative to the zone center, and we assumed that V is only slowly varying on the scale of the lattice constant. Here, $\boldsymbol{\sigma}$ is the vector of Pauli matrices for the pseudo spin-$\frac{1}{2}$ of the Kramer's doublet at $k = 0$; it is customarily called a *spin-$\frac{1}{2}$ system*. $\mathbf{b}(\mathbf{k})$ is the intrinsic spin-orbit field, with $\mathbf{b}(\mathbf{k}) = -\mathbf{b}(-\mathbf{k})$ due to time reversal symmetry. Thus, for a three-dimensional system, $\mathbf{b}$ can only be present if the inversion symmetry of the host crystal is broken. In the case of a two-dimensional system, it is conventional to talk about its two-dimensional band structure, and to include the confinement potential in ϵ_k and $\mathbf{b}(\mathbf{k})$ (instead of including it explicitly in V); in this case $\mathbf{b}$ can also result from an asymmetry in the confinement.

In contrast, H_{ext} does not require broken inversion symmetry of the pure crystal or of the structure. It is important to note that λ in equation (4) can be many orders of magnitude larger than the vacuum value λ_{vac}; this is due to the large spin-orbit interaction when the Bloch electrons move close to the nuclei, with velocities that are close to relativistic. Both H_{int} and H_{ext} may be important for the spin Hall effect, as we will discuss in this chapter. We present specific forms of these effective Hamiltonians in Sections 2.3 and 2.4.

2.1 Band structure of materials with spin-orbit interaction

We now consider the electron wave functions near the forbidden gap of a semiconductor. These wave functions are often described by the Kohn–Luttinger $\mathbf{k} \cdot \mathbf{p}$ method, where one expands the Hamiltonian in terms of band-edge Bloch functions. Here, we present a brief overview of this method; more detailed explanations can be found, for example, in Blount's (1962) review article or in the books by Bir and Pikus (1974) and by Winkler (2003).

For a given $\mathbf{k}$, the solutions of the Schrödinger equation are Bloch functions $e^{i\mathbf{k}\cdot\mathbf{r}} u_{\nu',\mathbf{k}}(\mathbf{r})$. Here, ν' is the band index and includes the spin degree of freedom. The lattice-periodic part $u_{\nu',\mathbf{k}}(\mathbf{r})$ of these Bloch functions can be expanded in the functions $u_{\nu,\,\mathbf{k}=0}(\mathbf{r}) = \langle \mathbf{r} | u_{\nu,0} \rangle$, which provide a complete basis when all bands ν are taken. For semiconductors with a direct gap at the center of the Brillouin zone, which we discuss here, one may consider states in close vicinity of $\mathbf{k} = 0$, truncate this expansion, and only take the closest bands into account. Therefore, it is sufficient to know the matrix elements of the full Hamiltonian H in the truncated basis $|\phi_\nu\rangle = e^{i\mathbf{k}\cdot\mathbf{r}} |u_{\nu,0}\rangle$, that is, one considers $H_{\nu\nu'}(\mathbf{k}) = \langle \phi_\nu | H | \phi_{\nu'} \rangle$. More concretely, one evaluates

$$H_{\nu\nu'}(\mathbf{k}) = E_\nu \delta_{\nu\nu'} + \frac{\hbar^2 k^2}{2m_0}\delta_{\nu\nu'} + \frac{\hbar}{m_0}\mathbf{k} \cdot \langle u_{\nu,0} | \boldsymbol{\pi} | u_{\nu',0} \rangle \tag{5}$$

where E_ν is the energy offset of the band at $\mathbf{k} = 0$, that is, $[p^2/2m_0 + V_{\text{cr}} + (\lambda_{\text{vac}}/\hbar)\,\boldsymbol{\sigma} \cdot (\mathbf{p} \times \nabla V_{\text{cr}})] |u_{\nu,0}\rangle = E_\nu |u_{\nu,0}\rangle$. Further, $\boldsymbol{\pi} = \mathbf{p} + (\lambda_{\text{vac}}/\hbar)\,(\nabla V_{\text{cr}} \times \boldsymbol{\sigma})$, and one usually approximates $\boldsymbol{\pi} \approx \mathbf{p}$; then the last term of equation (5) is proportional to the matrix element of $\mathbf{k} \cdot \mathbf{p}$, giving this method its name. Finally, this finite-dimensional Hamiltonian $H(\mathbf{k})$ now describes the band structure in terms of a few parameters – band offsets and momentum matrix elements of $\mathbf{k} = 0$ Bloch functions – and is well suited for analyzing charge carriers.

Alternatively, one can use a second method and construct a Hamiltonian by allowing all contributions (up to some order in k) that are invariant under the symmetry operations of the system – the coupling constants are material-dependent parameters. For example, when considering the top of the valence band in Figure 1 and in the absence of inversion asymmetry, magnetic field, and strain, the most general form up to quadratic terms in k (i.e., in the effective mass approximation), is the 4×4 Luttinger Hamiltonian,

$$H_{\text{L}} = \frac{\hbar^2}{m_0}\left[\left(\gamma_1 + \frac{5}{2}\gamma_2\right)\frac{k^2}{2} - \gamma_3 (\mathbf{k} \cdot \mathbf{J})^2 + (\gamma_3 - \gamma_2)\sum_{\text{i}} k_{\text{i}}^2 J_{\text{i}}^2\right] \tag{6}$$

which is consistent with the cubic symmetry. Here, $\mathbf{J} = (J_x, J_y, J_z)$ and J_{i} are the angular momentum matrices for spin $\frac{3}{2}$, and γ_{i} are the material-dependent Luttinger parameters. H_{L} describes p-doped Si and Ge; for GaAs, due to broken inversion symmetry, terms linear in k arise as well.

By contrast, using the first method ($\mathbf{k} \cdot \mathbf{p}$ method) instead, the Hamiltonian $H_{\nu\nu'}(\mathbf{k})$ (equation (5)) is evaluated directly for the eight bands ν (including spin) shown in Figure 1, and one arrives at the simplest version of the 8×8 Kane model. It only includes three parameters, namely, the energy gap E_0,

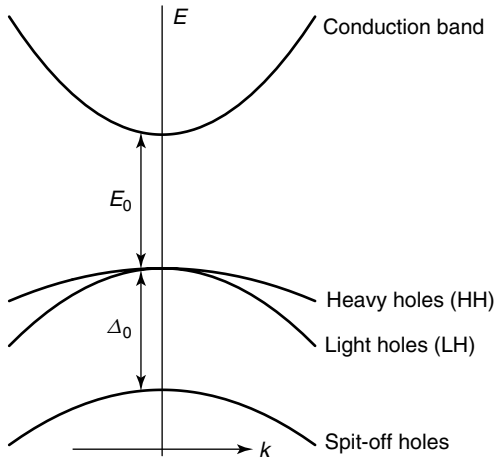

Figure 1. Schematic band structure of a cubic direct gap semiconductor. When spin-orbit interaction is disregarded, one finds an s-like conduction band and a p-like threefold degenerate valence band. The spin-orbit interaction due to crystal potential V_{cr} (entering as $\tilde{V}$ in equation (1)) partially lifts this degeneracy and leads to a substantial splitting between the valence bands with total angular momentum $J = 3/2$ (heavy and light holes) and those with $J = 1/2$ (split-off holes).

the energy of the split-off holes Δ_0, and the matrix element P of the momentum (multiplied by $\hbar/m_0$) between s- and p-type states. P is nearly universal for III–V compounds, while the other parameters depend on the material. This eight-dimensional description is accurate for narrow band materials; for wider gaps it still provides understanding at a qualitative level.

Furthermore, one can then derive an effective, lower-dimensional Hamiltonian by block diagonalizing $H_{\nu\nu'}$; this is an efficient way to calculate the band structure in the vicinity of $\mathbf{k} = 0$. One can do this either exactly or by using time-independent degenerate perturbation theory (see Section 2.2). Considering a particular block, this allows estimating the magnitude of the symmetry-allowed terms. Terms that were not present before block diagonalization are called contributions from remote bands. For example, using the 8×8 Kane model, one can calculate the parameters γ_{i} that enter the 4×4 Luttinger Hamiltonian (equation (6)) for the top of the valence band; because the model is isotropic, one gets $\gamma_2 = \gamma_3$. To estimate corrections due to the cubic symmetry, one needs to take more bands into account.

In addition to the crystal field, we also wish to consider electric fields that are applied externally or that result from charged impurities. Assuming that the corresponding potential $V(\mathbf{r})$ varies slowly on the scale of a lattice constant, we can apply the envelope function approximation (EFA), that is, we replace the plain waves $\mathrm{e}^{i\mathbf{k}\cdot\mathbf{r}}$ by slowly varying envelope functions $\psi_\nu(\mathbf{r})$. Evaluating matrix elements of V in the basis $\langle \mathbf{r}|\psi, \nu\rangle = \psi_\nu(\mathbf{r})u_{\nu,\,\mathbf{k}=0}(\mathbf{r})$, the main contribution is diagonal with respect to the band index ν. However, because $\mathbf{k}$ and $V(\mathbf{r})$ do not commute, off-diagonal elements (in ν) can arise in the Hamiltonian when expanding in $\mathbf{k}$, see, for example, equation (4). Magnetic fields can be included in a similar way, using the Perierls substitution $\hbar\mathbf{k} = -i\hbar\nabla - (e/c)\mathbf{A}$. Here, we use $e < 0$ for electrons and $e > 0$ for holes. Then, the components of $\mathbf{k}$ no longer commute, $\mathbf{k} \times \mathbf{k} = i(e/\hbar c)\mathbf{B}$; this leads to Zeeman coupling, which is described by an effective g factor.

2.2 Effective Hamiltonian

The $\mathbf{k}\cdot\mathbf{p}$ method leads to high-dimensional Hamiltonians (equation (5)), for example, an 8×8 matrix for the Kane model, thus further simplifications are desirable. For this, one can use time-independent degenerate perturbation theory and describe a subset of states (say, the lowest conduction-band states) with an effective Hamiltonian. Löwdin partitioning is a straightforward and convenient method to implement such a perturbative expansion (Winkler, 2003); it is also known as Foldy-Wouthuysen transformation in the context of the Dirac equation and as Schrieffer-Wolf transformation in the context of the Anderson model. The idea is to find a unitary transformation e^{-S} (i.e., S is anti-Hermitian) such that the transformed Hamiltonian $\mathrm{e}^{-S}H\mathrm{e}^{S}$ is block diagonal, that is, contains no off-diagonal elements between the states we are interested in and any other states. This procedure assumes that the states of interest (e.g., the conduction band) are separated from the other states (all other bands) by an energy much larger than the Fermi energy. Then, because these off-diagonal elements are small, one can eliminate the off-diagonal blocks of $\mathrm{e}^{-S}H\mathrm{e}^{S}$ order by order (or even exactly). In our example, the transformed Hamiltonian consists of one 2×2 and one 6×6 block. The smaller block describes the conduction-band electrons – we can understand the two dimensions as (pseudo-) spin $\frac{1}{2}$. At the level of wave functions, the periodic part of the electron wave function at a given $\mathbf{k} \neq 0$ is mainly described by the conduction band Bloch function at $k = 0$, but also contains a small admixture from the valence band Bloch functions.

2.3 Intrinsic spin-orbit coupling

One generally distinguishes between intrinsic and extrinsic mechanisms of spin-orbit coupling; however, this classification is not unique across the literature. In this section, we classify it according to the individual terms of the effective Hamiltonians. Namely, we refer to the spin-orbit contributions to the Hamiltonian that depend on impurity potentials as *extrinsic*. The other spin-orbit contributions arise even in the

absence of impurities and we call them *intrinsic* – we also call effects resulting from these contributions intrinsic, even if we have to allow for a small concentration of impurities to make the theory of dc transport properties consistent [1].

For a (pseudo-) spin-$\frac{1}{2}$ system, the spin-orbit part of the intrinsic one-particle Hamiltonian has the general form $H_{\rm int}$ (equation (3)). In the following, we discuss the origin and the functional form of such spin-orbit fields. We focus on such spin-$\frac{1}{2}$ descriptions, because they are relevant for low-dimensional systems and are the basis of most theoretical works.

We first consider a n-doped bulk (3D) semiconductor and the effective Hamiltonian of conduction-band electrons. III–V and II–VI semiconductors lack inversion symmetry and are available in two modifications: in cubic zinc blende or in hexagonal wurtzite structure. In zinc blende modification, the bulk inversion asymmetry (BIA) leads to the Dresselhaus term

$$H_{\rm D,\,3d} = \mathcal{B}\, k_x (k_y^2 - k_z^2)\sigma_x + \text{c.p.} \tag{7}$$

where $k_{\rm i}$ are along the principal crystal axes. Here, c.p. stands for cyclic permutation of all indices, and the symmetrized product of the components $k_{\rm i}$ must be used if a magnetic field is applied. The Dresselhaus term originates from bands further away than the basic eight bands, and one finds the coupling constant in terms of the band parameters; when using the extended 14×14 Kane model its numerical value is $\mathcal{B} \approx 27\ \text{eV\AA}^3$, for both GaAs and InAs (Winkler, 2003). However, tight-binding calculations and interpretation of weak-localization experiments indicate lower values, at least for GaAs (Knap *et al.*, 1996; Krich and Halperin, 2007).

When the electrons are confined to two dimensions, the expectation value of the Dresselhaus term along the confinement direction (that we always assume to be along [001]) should be taken, $\langle H_{\rm D,\,3d}\rangle$. While $\langle k_z\rangle = 0$, we see that the terms in $\langle k_z^2\rangle \approx (\pi/d)^2$ are large for small confinement width d, thus the main BIA contribution becomes

$$H_\beta = \beta(k_x\sigma_x - k_y\sigma_y) \tag{8}$$

with $\beta \approx -\mathcal{B}(\pi/d)^2$. In addition to the k-linear term in equation (8), there is also a k^3 term,

$$H_{\rm D,\,2d} = \mathcal{B}\, k_x k_y (k_y\sigma_x - k_x\sigma_y) \tag{9}$$

which is small compared to H_β in the strong confinement (low carrier density) limit $\pi/d \gg k_{\rm F}$, where $k_{\rm F}$ is the Fermi wave vector. Additionally, a spin-orbit coupling term arises if the confinement potential $V(z)$ along the z direction is not symmetric, that is, if there is a structure inversion asymmetry (SIA). Equation (4) provides an explicit connection between such a potential and spin-orbit coupling. Taking the expectation value $\langle H_{\rm ext}\rangle$ along the z direction and noting that the only contribution of the confinement field is $\propto \langle \nabla_z V\rangle$, one finds the Rashba Hamiltonian,

$$H_\alpha = \alpha(k_y\sigma_x - k_x\sigma_y) \tag{10}$$

corresponding to $\mathbf{b}(\mathbf{k}) = 2\alpha\,\hat{\mathbf{z}}\times\mathbf{k}$. More generally, for spinors with $J_z = \pm 1/2$, H_α is the only k-linear invariant of the group $C_{\infty v}$ that takes into account the confinement potential $V(z)$ but disregards the discrete symmetry of the crystal. The magnitude of the coupling constant α depends on the confining potential and it can be modified by applying an additional field via external gates. It also defines the spin-precession wave vector $k_\alpha = \alpha m/\hbar^2$. Finally, such a term H_α is also present for three-dimensional electrons in systems of hexagonal wurtzite structure (or in cubic systems with strain, see Section 2.5).

Next, we consider a p-doped three-dimensional semiconductor, that is, the $J = 3/2$ valence band, described by the four-dimensional Luttinger Hamiltonian. Remote bands lead to a BIA contribution to the Hamiltonian, which is given by equation (7) after replacing $\sigma_{\rm i}$ by the angular momentum matrices $J_{\rm i}$ for spin $\frac{3}{2}$ and using a different coupling constant. If the system is reduced to two dimensions, size quantization lifts the fourfold degeneracy at $\mathbf{k} = 0$ and creates heavy-hole (HH) bands with $J_z = \pm 3/2$ and light-hole (LH) bands with $J_z = \pm 1/2$ (for confinement along the [001] axis). Usually the HH bands are higher in energy, thus for small doping it is sufficient to consider only them. For spinors with $J_z = \pm 3/2$, the only invariant of the group $C_{\infty v}$ (again, we do not discuss invariants of discrete symmetries here) respecting time reversal symmetry is

$$H_{\alpha,\rm h} = i\alpha_{\rm h}\left(k_-^3\sigma_+ - k_+^3\sigma_-\right) \tag{11}$$

where $a_\pm \equiv a_x \pm i a_y$ for any a. As distinct from H_α (equation (10)), the Rashba Hamiltonian for HHs is cubic in k, as it was discussed in (Winkler, 2000; Schliemann and Loss, 2005).

2.4 Extrinsic spin-orbit coupling

Electric fields due to impurities lead to extrinsic contributions to the spin-orbit coupling. Externally applied electrical fields lead to analogous contributions. To derive the dominant extrinsic term, it is sufficient to restrict ourselves to the simplest 8×8 Kane Hamiltonian; higher bands will give rise to small corrections. Using third-order perturbation theory and for conduction-band electrons, we find $H_{\rm ext}$ as given in equation (4), with (Nozières and Lewiner, 1973;

Winkler, 2003)

$$\lambda \approx \frac{P^2}{3}\left[\frac{1}{E_0^2} - \frac{1}{(E_0+\Delta_0)^2}\right] \tag{12}$$

and where V is the potential due to impurities and an externally applied field. It is noteworthy that equation (4) has the same analytical form as the vacuum spin-orbit coupling (equation (1)); this is because both the Dirac equation and the simplest Kane Hamiltonian have spherical symmetry and because both the Pauli equation and equation (4) are obtained in a low-energy expansion. However, for $\Delta_0 > 0$ the coupling constant λ has the *opposite sign* as in vacuum.

One finds $\lambda \approx 5.3\,\text{Å}^2$ for GaAs and $\lambda \approx 120\,\text{Å}^2$ for InAs, that is, spin-orbit coupling in n-GaAs is by 6 orders of magnitude stronger than in vacuum, and even larger for InAs due to its smaller gap. This enhancement of spin-orbit coupling is critical for developing large extrinsic spin currents. Furthermore, for a two-dimensional system, when considering V as averaged along the $\hat{\mathbf{z}}$ direction, both ∇V and $\mathbf{k}$ are in plane, thus we have $H_{\text{ext, e}} = \lambda\,\sigma_z(\mathbf{k}\times\nabla V)_z$.

For a 3D hole system, we consider the $J = 3/2$ valence band. Then, the dominant extrinsic spin-orbit term in third-order perturbation theory describing the valence band states is

$$H_{\text{ext, v}} = \lambda_{\text{v}}\,\mathbf{J}\cdot(\mathbf{k}\times\nabla V) \tag{13}$$

with $\lambda_{\text{v}} = -P^2/3E_0^2$, that is, for GaAs $\lambda_{\text{v}} \approx -15\,\text{Å}^2$ (Winkler, 2003) and has to be added to the Luttinger Hamiltonian H_{L} (equation (6)). When considering a two-dimensional hole system with HH–LH splitting, we can restrict equation (13) to the HH states, where $J_z = \pm 3/2$. Expressing this two-dimensional subspace in terms of a pseudo spin $\frac{1}{2}$ leads to

$$H_{\text{ext, v}} = -\frac{P^2}{2E_0^2}\,(\mathbf{k}\times\nabla V)_z\sigma_z \tag{14}$$

Thus, the extrinsic spin-orbit interaction for two-dimensional HH states has the same form as for two-dimensional electrons.

Finally, we point out that extrinsic spin-orbit coupling arises because the long-range Coulomb potential of the impurities does not commute with the intrinsic Hamiltonian of the hosting crystal. The extrinsic Hamiltonian H_{ext} (equations (4) and (13)) is obtained in the framework of the EFA, which disregards short-range contributions to the spin-orbit coupling arising from the chemical properties of dopants. This is why the coupling λ depends only on the parameters of the perfect crystal lattice.

2.5 Strain

Nonhydrostatic strain reduces the symmetry of the system and in this way leads to additional spin-orbit terms in the Hamiltonian. In third-order perturbation theory of the Kane Hamiltonian, the effective conduction-band Hamiltonian due to strain is dominated by

$$H_{\varepsilon,\,\text{e}} = \frac{-2C_2\Delta_0 P}{3E_0(E_0+\Delta_0)}\,\boldsymbol{\sigma}\cdot(\mathbf{k}\times\boldsymbol{\varepsilon}_{\text{s}}) \equiv \frac{1}{2}C_3\,\boldsymbol{\sigma}\cdot(\mathbf{k}\times\boldsymbol{\varepsilon}_{\text{s}}) \tag{15}$$

where $\boldsymbol{\varepsilon}_{\text{s}} = (\varepsilon_{yz},\ \varepsilon_{xz},\ \varepsilon_{xy})$ describes the shear strain. Here, C_2 is the interband deformation-potential constant that arises in noncentrosymmetric semiconductors (Winkler, 2003; Trebin, Rössler and Ranvaud, 1979). Note that Pikus and Titkov (1984) as well as Ivchenko and Pikus (1997) use the opposite sign in the definition of this constant, $C_2^{\text{PT/IP}} = -C_2$. Further, if a shear is applied such that only $\varepsilon_{xy} \neq 0$, equation (15) has the same form as the Rashba Hamiltonian (equation (10)).

For three-dimensional $J = 3/2$ valence band states, the main strain contribution is (Pikus and Titkov, 1984)

$$H_{\varepsilon,\,\text{v}} = \frac{2C_2P}{3E_0}\,\mathbf{J}\cdot(\mathbf{k}\times\boldsymbol{\varepsilon}_{\text{s}}) \tag{16}$$

Note that when the system is confined to two dimensions, equation (16) implies a k-linear spin-orbit contribution for HH states due to strain, $(C_2P/E_0)\ (\mathbf{k}\times\boldsymbol{\varepsilon}_{\text{s}})_z\,\sigma_z$. This linear term arises due to the low symmetry of the strained material, in contrast to the Rashba term (cf. equation (11)), which is dominated by terms cubic in k and where the k-linear terms are numerically small (Winkler, 2003).

2.6 Anomalous velocity and coordinate

As a consequence of the spin-orbit interaction, velocity and coordinate operators are modified and become spin dependent – this will be important when considering currents. When an effective Hamiltonian is derived in perturbation theory, as explained in Section 2.2, a unitary transformation e^{-S} is applied. Thus, the coordinate operator $\mathbf{r} = i(\partial/\partial\mathbf{k})$ is also transformed, $\mathbf{r}\mapsto\tilde{\mathbf{r}} = \text{e}^{-S}\mathbf{r}\text{e}^{S} = \mathbf{r} + \delta\mathbf{r}$ and we call $\delta\mathbf{r}$ the anomalous coordinate. In particular, because S couples to spin, $\delta\mathbf{r}$ is spin dependent. This correction $\delta\mathbf{r}$ is known as the *Yafet term* (Yafet, 1963); also, it can be expressed in terms of a Berry connection, $\langle u_{v',\mathbf{k}}\,|i\nabla_{\mathbf{k}}|\,u_{v,\mathbf{k}}\rangle$ (Kohmoto, 1985; Sundaram and Niu, 1999; Nagaosa, 2006). In perturbation theory, one finds

$$\delta\mathbf{r}_{\text{SO, e}} = \lambda(\boldsymbol{\sigma}\times\mathbf{k}) \tag{17}$$

$$\delta\mathbf{r}_{\text{SO, v}} = \lambda_{\text{v}}(\mathbf{J}\times\mathbf{k}) \tag{18}$$

for conduction-band electrons and for $J = 3/2$ HH states, respectively. Note that coordinate operators no longer commute, $\mathbf{r} \times \mathbf{r} = i\lambda\boldsymbol{\sigma}$ and $\mathbf{r} \times \mathbf{r} = i\lambda_{\mathrm{v}}\mathbf{J}$, respectively. Finally, $\delta\mathbf{r}_{\mathrm{SO}}$ leads to an extra term in the equations of motion that can be understood as anomalous velocity (Blount's, 1962).

Formally, we can derive the anomalous velocity similar to the coordinate, namely, $\mathbf{v} \mapsto \mathrm{e}^{-S}\mathbf{v}\mathrm{e}^{S} = \mathbf{v}_0 + \delta\mathbf{v}$, where $\delta\mathbf{v}$ is the anomalous velocity and, for a parabolic band, $\mathbf{v}_0 = \hbar\mathbf{k}/m^*$. Alternatively, one can obtain the velocity operator from the Heisenberg equation, $\mathbf{v} = (i/\hbar)\left[H, \tilde{\mathbf{r}}\right]$. For $H = H_0 + H_{\mathrm{SO}}$, where H_{SO} contains the (small) spin-orbit coupling, we get $\mathbf{v} = \mathbf{v}_0 + (i/\hbar)\,[H_{\mathrm{SO}}, \mathbf{r}] + (i/\hbar)\,[H_0, \delta\mathbf{r}_{\mathrm{SO}}]$. Thus, H_{SO} leads to an anomalous velocity because it does not commute with the unperturbed coordinate $\mathbf{r}$, and, additionally, the contribution from the anomalous coordinate $\delta\mathbf{r}_{\mathrm{SO}}$ should also be taken into account, as it can be significant.

When the impurity potential V is included, the above argument remains the same, but now H_{SO} contains the extrinsic contribution as well. Note that for extrinsic spin-orbit $H_{\mathrm{SO}} = H_{\mathrm{ext,\,e}}$ (equation (4)) the commutator $\left[H_{\mathrm{ext,\,e}}, \mathbf{r}\right]$ and the anomalous coordinate $\delta\mathbf{r}_{\mathrm{SO}}$ give equal contributions to $\delta\mathbf{v}$ (Nozières and Lewiner, 1973).

3 MECHANISMS OF SPIN TRANSPORT

We now address how the microscopic mechanism of spin-orbit interaction, given by effective Hamiltonians, influences spin transport and accumulation. In the following, we assume a noninteracting system in the absence of a magnetic field. Because we ignore electron–electron interaction, we do not consider the spin-drag effect here (Hankiewicz and Vignale, 2006), which can lead to a suppression of spin transport at high temperatures, and suppression of spin relaxation (Glazov and Ivchenko, 2002). We also restrict ourselves to Boltzmann transport and do not discuss the hopping regime (Entin-Wohlman *et al*., 2005).

3.1 Intrinsic: spin precession

In a system with weak intrinsic spin-orbit coupling H_{int} (equation (3)), consider a carrier with spin aligned along the spin-orbit field $\mathbf{b}(\mathbf{k})$. When an electrical field $\mathbf{E} = E\hat{\mathbf{x}}$ is applied, the particle is accelerated: $\dot{\mathbf{k}} = e\mathbf{E}/\hbar$ in lowest order in spin-orbit interaction; and its spin-orbit field changes: $\dot{\mathbf{b}} = (\partial\mathbf{b}/\partial k_x)\,eE/\hbar$. For a small acceleration, the spin follows adiabatically the direction of $\mathbf{b}(\mathbf{k})$. Additionally, there will be a nonadiabatic correction that can be derived as follows. Suppose that the direction of $\mathbf{b}$ rotates in the xy plane (as it is the case for Rashba interaction H_α). Because the rotation frequency ω is the component of $\dot{\mathbf{b}}/b$ perpendicular to $\mathbf{b}$, it is $\omega = (\mathbf{b} \times \dot{\mathbf{b}})_z/b^2$. In the corotating frame, there is a field b along the x axis and a field $\hbar\omega$ along the z axis. As we are interested in the next-to-adiabatic correction, we assume that ω changes slowly and that the spin remains aligned along the total field in the rotating frame, thus it has a component $s_z \approx (\hbar/2)\,\hbar\omega/b$. Therefore, the first nonadiabatic correction to the spin is $\delta\mathbf{s}(\mathbf{k}) = \hbar^2(\mathbf{b} \times \dot{\mathbf{b}})_z/2b^3$. In particular, the electrical field drives this spin precession (via $\dot{\mathbf{b}}$), leading to such out-of-plane component $\delta\mathbf{s}(\mathbf{k})$, which could be important in spin transport (Sinova *et al*., 2004), see Section 4.3. However, when considering dc properties, one must be careful and also allow for impurities that decelerate the carriers to reach a steady state. In particular, if $\mathbf{b}(\mathbf{k})$ is linear in $\mathbf{k}$, it turns out that the deceleration at impurities cancels this spin precession, see Section 4.3.

3.2 Extrinsic: skew scattering

When a carrier scatters at an impurity potential V, because of the extrinsic spin-orbit interaction (equations (4) and (14)) the scattering cross section depends on the spin state (Smit, 1958), see Figure 2. This effect is known as *Mott skew scattering* (Mott and Massey, 1965) and was originally considered for high-energy electrons that are elastically scattered by an atom and that are described by the vacuum Hamiltonian, equation (1). Skew scattering does not appear in the first-order Born approximation, thus is at least of the order V^3. For band electrons, skew scattering was originally considered as the origin of the anomalous Hall

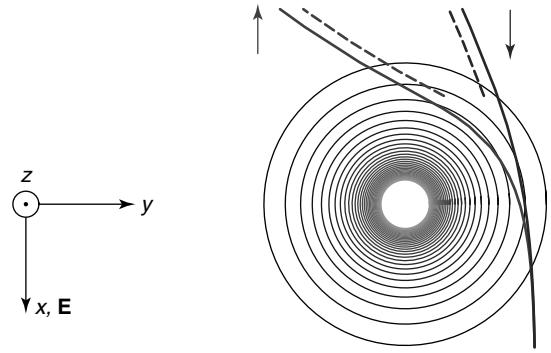

Figure 2. Spin-dependent scattering of electrons at an attractive impurity. We show the classical trajectories (solid lines), for a screened Coulomb potential and for strongly exaggerated extrinsic spin-orbit coupling (using equation (4) with $\lambda > 0$) and with spin quantization axis perpendicular to the plane. The skew-scattering current results from different scattering angles for spin-↑ and spin-↓ electrons and leads to a positive spin Hall conductivity, $\sigma_{\mathrm{SS}}^{\mathrm{SH}} = -j_{\mathrm{SS},y}^{z}/E_x > 0$. The dashed lines show the horizontal displacement due to the side-jump effect, contributing to the spin current with opposite sign.

effect, see Section 4.4. As applied to spin Hall effect, the relevance of this extrinsic mechanism was recognized early on (D'yakonov and Perel', 1971; Hirsch, 1999; Zhang, 2000).

3.3 Extrinsic: side-jump mechanism

The side-jump mechanism (Berger, 1970) describes the lateral displacement of the wave function during the scattering event. (Such a displacement does not modify the skew scattering cross section introduced in Section 3.2, because it does not change the scattering angle measured at large distances.) The side-jump contribution is obtained when the anomalous velocity $\delta\mathbf{v}$ (see Section 2.6) is integrated over the duration of the scattering process. As indicated in Section 2.6, the anomalous coordinate for electrons (equation (17)) leads to an anomalous-velocity contribution $\lambda(\boldsymbol{\sigma} \times \dot{\mathbf{k}})$; and there is an equal term due to $(i/\hbar)[H_{\mathrm{ext,\,e}},\ \mathbf{r}]$. For impurity scattering with momentum transfer $\delta\mathbf{k}$, this results in a total lateral displacement $2\lambda(\boldsymbol{\sigma} \times \delta\mathbf{k})$ (and analogously for holes, using equation (18)). When the effect of the anomalous velocity owing to an applied electrical field is considered, the side-jump contribution to spin transport becomes a subtle issue; for a detailed analysis and intuitive description see (Nozières and Lewiner, 1973). Because the side-jump mechanism is not contained in the Boltzmann approach, in such a framework it needs to be evaluated separately. The side-jump contribution can be found using the Kubo formula and diagrammatic approaches; see (Lewiner, Betbeder and Nozières, 1973; Crépieux and Bruno, 2001; Tse and Das Sarma, 2006a).

3.4 Kinetic equation

We consider the Hamiltonian H_{eff} (equation (2)) containing both intrinsic (H_{int}) and extrinsic (H_{ext}) spin-orbit contributions, and with V that describes the electrical field $\mathbf{E}$ and the impurity potential V_{i}. For a homogeneous system of noninteracting particles, one can derive the kinetic equation (Khaetskii, 2006; Shytov, Mishchenko, Engel and Halperin, 2006)

$$\frac{\partial \hat{f}}{\partial t} + \frac{1}{\hbar}\,\boldsymbol{\sigma}\cdot(\mathbf{b}\times\mathbf{f}) + e\mathbf{E}\cdot\frac{1}{\hbar}\frac{\partial \hat{f}_0}{\partial \mathbf{k}} = \left(\frac{\partial \hat{f}}{\partial t}\right)_{\mathrm{coll}} \tag{19}$$

that is, a spin-dependent Boltzmann equation, where the distribution function is written as a 2×2 spin matrix $\hat{f} = \hat{f}_0(\mathbf{k}) + \frac{1}{2}n(\mathbf{k})\,\mathbb{1} + \mathbf{f}(\mathbf{k})\cdot\boldsymbol{\sigma}$, with equilibrium distribution function $\hat{f}_0$. Here, n is the excess particle density and $\mathbf{f}$ describes the spin-polarization density. Formally, the Boltzmann equation is obtained by an expansion in $1/k_{\mathrm{F}}\ell$, where ℓ is the mean free path, that is, it is applicable for dilute impurities. Traditionally, the Boltzman equation describes the distribution function $n(\mathbf{k})$, which is the *probability* density of a state $\mathbf{k}$ to be occupied – in contrast, here it describes $\hat{f}(\mathbf{k})$, which corresponds to the 2×2 *density matrix* for a spin-$\frac{1}{2}$ particle.

All terms on the lhs of equation (19) arise in the absence of impurities. The first term is the derivative of $\hat{f}$ with respect to its explicit time dependence. The second term describes the spin precession; it is obtained from the Heisenberg equation, $\mathbf{f}\cdot\dot{\boldsymbol{\sigma}} = \mathbf{f}\cdot(i/\hbar)\left[-\frac{1}{2}\mathbf{b}\,(\mathbf{k})\cdot\boldsymbol{\sigma},\ \boldsymbol{\sigma}\right]$. The third term is the driving term due to the electrical field, given in lowest order of $\mathbf{E}$. Finally, for inhomogeneous particle and spin distributions, the term $\mathbf{v}\cdot\nabla\hat{f}$ has to be added to the lhs.

The rhs of the Boltzmann equation (equation (19)) is the collision term, symbolically given by

$$\left(\frac{\partial \hat{f}(\mathbf{k})}{\partial t}\right)_{\mathrm{coll}} = n_{\mathrm{i}} v \sum_{\mathbf{k}';\ \epsilon'=\epsilon} \frac{\mathrm{d}\overleftrightarrow{\sigma}}{\mathrm{d}\Omega}\left[\hat{f}(\mathbf{k}') - \hat{f}(\mathbf{k})\right] \tag{20}$$

Here, n_{i} is the impurity density and we only consider elastic scattering $\mathbf{k}\to\mathbf{k}'$ and $\mathbf{k}'\to\mathbf{k}$. The scattering cross-section tensor $\mathrm{d}\overleftrightarrow{\sigma}/\mathrm{d}\Omega$ and the summation over final states $\mathbf{k}'$ are spin dependent because (i) the extrinsic interaction H_{ext} leads to skew scattering, (ii) the intrinsic spin-orbit Hamiltonian H_{int} induces a spin-dependent density of states (DOS), and (iii) H_{int} causes spin-dependent momentum transfer – in general, the spin dependence of scattering is rather complex. The description of scattering is simplified for weak spin orbit coupling, as the collision term can be expanded in spin-orbit coupling, and we can discuss the individual corrections separately. Note that the Boltzmann equation does not include the side-jump effect (cf. Section 3.3), which is of higher order in $1/k_{\mathrm{F}}\ell$.

When considering only spin-orbit coupling due to H_{ext}, the collision term including skew scattering for a central symmetric impurity potential is (Engel, Halperin and Rashba, 2005)

$$\left(\frac{\partial \hat{f}(\mathbf{k})}{\partial t}\right)_{\mathrm{coll}} = n_{\mathrm{i}} v_\epsilon \int \mathrm{d}\Omega(\mathbf{k}')\left\{I(\vartheta)\left[\hat{f}(\mathbf{k}') - \hat{f}(\mathbf{k})\right] + \frac{1}{2}I(\vartheta)S(\vartheta)\,\boldsymbol{\sigma}\cdot\mathbf{m}[n(\mathbf{k}) + n(\mathbf{k}')]\right\} \tag{21}$$

where $\mathbf{m} = \mathbf{k}'\times\mathbf{k}/\left|\mathbf{k}'\times\mathbf{k}\right|$ is the unit vector normal to the scattering plane and $\vartheta = \vartheta_{\mathbf{k}\mathbf{k}'}$ is the angle between $\mathbf{k}'$ and $\mathbf{k}$. The coefficient $I(\vartheta)$ is the spin-independent part of the scattering cross section, while $S(\vartheta)$ is the so-called Sherman function (Mott and Massey, 1965; Motz, Olsen and Koch, 1964; Huang, Voskoboynikov and Lee, 2003), describing the polarization of outgoing particles (which is

normal to the scattering plane) scattered into direction $\mathbf{k}$ from an unpolarized incoming beam of momentum $\mathbf{k}'$. Note that $I\,S$, as mentioned earlier in Section 3.2, vanishes in first-order Born approximation; the lowest term is $\propto V^3$. Also, S is proportional to spin-orbit coupling, this is why in the second term in equation (21), only the spin-independent part of $\hat{f}$, $\frac{1}{2}n$, is retained.

So far, we considered the distribution function $\hat{f}(\mathbf{k})$ as density in $\mathbf{k}$ space. In the presence of intrinsic spin-orbit interaction, the energy spectrum contains two branches: for a given $\mathbf{k}$, there are two energies, split by the intrinsic field $\mathbf{b}(\mathbf{k})$. Thus, for elastic scattering, energy is conserved but $|\mathbf{k}|$ is not. It is now more convenient to choose a distribution as function of energy ϵ and direction φ in $\mathbf{k}$ space. Namely, the distributions $\Phi_{\mathrm{c}}(\varphi,\,\epsilon)$ and $\mathbf{\Phi}(\varphi,\,\epsilon)$ are derived from the distributions $n(\mathbf{k})$ and $\mathbf{f}(\mathbf{k})$, and can again be written as matrix $\hat{\Phi}(\varphi,\,\epsilon)$. Note that $\hat{\Phi}$ contains the spin-dependent DOS. We now consider a two-dimensional system, $\mathbf{k} = (k\cos\varphi,\ k\sin\varphi)$, and assume that the spectrum ϵ_k in the absence of spin-orbit interaction is isotropic (cf. equation (2)), and we define k_ϵ such that $\epsilon_{k_\epsilon} = \epsilon$ and define $v_\epsilon = \epsilon'_{k_\epsilon}/\hbar$. For $\mathbf{E} = E\hat{\mathbf{x}}$ and for $b \ll E_{\mathrm{F}}$, the kinetic equation becomes (Shytov, Mishchenko, Engel and Halperin, 2006)

$$\frac{\partial\hat{\Phi}}{\partial t} + \boldsymbol{\sigma}\cdot\left[\frac{\mathbf{b}\times\mathbf{\Phi}}{\hbar} - \frac{\Phi_{\mathrm{c}}}{4\hbar^2 v_\epsilon}\,\mathbf{b}\times\frac{\partial\mathbf{b}}{\partial k}\right] + \frac{eE}{(2\pi)^2}\,\frac{\partial f_0}{\partial\epsilon}\left[\frac{k_x}{\hbar} + \frac{1}{2\hbar^2 v_\epsilon}\,\frac{\partial}{\partial\varphi}\,(\mathbf{b}\cdot\boldsymbol{\sigma}\,\sin\varphi)\right] = \left(\frac{\partial\hat{\Phi}}{\partial t}\right)_{\mathrm{coll}} \tag{22}$$

where f_0 is the Fermi distribution function and $\mathbf{b}$ is evaluated for $|\mathbf{k}| = k_\epsilon$.

Now, considering only H_{int}, the collision integral can be found in a Golden Rule approximation (Shytov, Mishchenko, Engel and Halperin, 2006),

$$\left(\frac{\partial\hat{\Phi}(\varphi,\,\epsilon)}{\partial t}\right)_{\mathrm{coll}} = \int_0^{2\pi}\mathrm{d}\varphi'\,K(\vartheta)\left[\hat{\Phi}(\varphi') - \hat{\Phi}(\varphi)\right] + \int_0^{2\pi}\mathrm{d}\varphi'\,\boldsymbol{\sigma}\cdot\left[\mathbf{M}(\varphi,\varphi')\Phi_{\mathrm{c}}(\varphi') - \mathbf{M}(\varphi',\varphi)\Phi_{\mathrm{c}}(\varphi)\right] \tag{23}$$

Here, the first term describes the spin-independent scattering, with $K(\vartheta) = K(\varphi'-\varphi) = W(q)k_\epsilon/2\pi\hbar^2 v_\epsilon$ and $q = 2k_\epsilon\sin(|\vartheta|/2)$. The factor $W(q) = \left\langle\,|V_{\mathrm{i}}(\mathbf{q})|^2\,\right\rangle$ does not depend on the direction of the momentum transfer $\mathbf{q}$ because the problem is isotropic (while, of course, the individual scattering event is anisotropic, that is, depends on the scattering angle ϑ). This spin-independent term coincides with first term of equation (21), with $K(\vartheta) = n_{\mathrm{i}}v_\epsilon I(\vartheta)$, and should only be included once. The second term in equation (23) is given in first order in the intrinsic spin-orbit interaction $\mathbf{b}$ and contains the kernel (Shytov, Mishchenko, Engel and Halperin, 2006)

$$\mathbf{M}(\varphi,\varphi') = \frac{v_\epsilon}{4k_\epsilon}\,K(\vartheta)\,\frac{\partial}{\partial\epsilon}\left[\frac{k_\epsilon\mathbf{b}(\varphi)}{v_\epsilon}\right] + \frac{\mathbf{b}(\varphi)+\mathbf{b}(\varphi')}{4\hbar k_\epsilon v_\epsilon}\,\frac{\partial K(\vartheta)}{\partial\vartheta}\,\tan\frac{\vartheta}{2} \tag{24}$$

where the first term results from the spin-dependent DOS of the outgoing wave. The second term in $\mathbf{M}$ arises, because for a given energy ϵ, $|\mathbf{k}|$ depends on the spin state. Thus the incoming and outgoing states can have different momenta, leading to spin-dependent corrections to q.

For a very smooth scattering potential such that typically $q < b/v_{\mathrm{F}}$, the spin motion is adiabatic and should be treated differently (Govorov, Kalameitsev and Dulka, 2004; Khaetskii, 2006).

3.5 Diffusion equation

A spin-diffusion equation can be derived, starting from the Boltzmann equation, for a dirty system when the spin-relaxation time τ_{s} is much longer than the momentum relaxation time τ, that is, $\tau_{\mathrm{s}} \gg \tau$. It describes the carrier density $N(\mathbf{r})$ and spin-polarization density $\mathbf{s}(\mathbf{r})$; say, s_z is the excess density of particles polarized along $\hat{\mathbf{z}}$. For conduction-band electrons, the (pseudo-) spin density is $\mathbf{S} = (\hbar/2)\mathbf{s}$. The diffusion equation is simpler to solve than the kinetic equation (19), as the dependence on $\mathbf{k}$ is integrated out. Also, it is usually sufficient to know $\mathbf{s}$, because it is an experimentally accessible quantity, while $\hat{f}(\mathbf{k})$ is not directly accessible, cf. Sections 4.2 and 4.5 below. For a two-dimensional system with Rashba spin-orbit interaction H_α (equation (10)), the diffusion equation is (Burkov, Núñez and MacDonald, 2004; Mishchenko, Shytov and Halperin, 2004)

$$\dot{N} = D\nabla^2(N + \rho_0 V_{\mathrm{E}}) + \Gamma_{\mathrm{sc}}(\nabla\times\mathbf{s})_z \tag{25}$$

$$\dot{s}_i = D\nabla^2 s_i - \tau_i^{-1}s_i + \Gamma_{\mathrm{ss}}[(\hat{\mathbf{z}}\times\nabla)\times\mathbf{s}]_i + \Gamma_{\mathrm{sc}}\,(\hat{\mathbf{z}}\times\nabla)_i(N + \rho_0 V_{\mathrm{E}}) \tag{26}$$

with diffusion constant $D = \frac{1}{2}v_{\mathrm{F}}^2\tau$, anisotropic Dyakonov–Perel (1972) spin-relaxation rates $\tau_x^{-1} = \tau_y^{-1} = \tau_\perp^{-1} = 2\tau(\alpha k_{\mathrm{F}}/\hbar)^2$ and $\tau_z^{-1} = 2\tau_\perp^{-1}$, spin-charge coupling $\Gamma_{\mathrm{sc}} = -2\alpha(\alpha k_{\mathrm{F}}\tau)^2/\hbar^3$, spin–spin coupling

$\Gamma_{\rm ss} = 4\alpha E_{\rm F}\tau/\hbar^2$, density of states $\rho_0 = m/\pi\hbar^2$, and potential energy $V_{\rm E}$ of a carrier in the electrical field. The charge current is

$$\mathbf{J}^{\rm c} = -D\nabla(N + \rho_0 V_{\rm E}) + \Gamma_{\rm sc}\,\hat{\mathbf{z}} \times \mathbf{s} \tag{27}$$

Further, Mal'shukov, Wang, Chu and Chao (2005) derived diffusion equations for two-dimensional electrons with the Dresselhaus Hamiltonian $H_{\rm D,\,2d}$ (equation (9)).

The boundary conditions of the diffusion equation for a system with spin-orbit interaction are not trivial and one expects that they depend on the microscopic properties of the boundaries. A number of papers have been written about the boundary conditions corresponding to various physical circumstances, and have partly clarified this issue (Govorov, Kalameitsev and Dulka, 2004; Mal'shukov, Wang, Chu and Chao, 2005; Adagideli and Bauer, 2005; Galitski, Burkov and Das Sarma, 2006; Bleibaum, 2006; Tserkovnyak, Halperin, Kovalev and Brataas, 2006). Depending on the particular boundary condition, there may or may not be an s_z spin accumulation near the boundary of a 2D system, see Section 4.5. Somewhat related to this question, Shekhter, Khodas and Finkel'stein (2005) considered the boundary between a diffusive and ballistic system and allowed for spin-dependent scattering at the boundary, resulting from a spatially dependent Rashba Hamiltonian H_α.

4 ELECTRICALLY INDUCED SPIN POLARIZATION AND SPIN TRANSPORT

4.1 Spin current and spin Hall conductivity

In this section, we define the spin current in a homogeneous system with density n as

$$j_k^i \equiv \frac{1}{2}\, n\langle \sigma_{\rm i} v_k + v_k \sigma_{\rm i}\rangle \tag{28}$$

where $\langle\cdot\rangle$ is the expectation value of single-particle operators and with $\langle 1\rangle = 1$. Thus, the spin current is defined as the difference of the particle current densities (measured in numbers of particles) for carriers with opposite spins. This is in accordance with many studies (Murakami, Nagaosa and Zhang, 2003; Sinova *et al*., 2004; Sinova, Murakami, Shen and Choi, 2006), where a definition as in equation (28) was chosen, up to numerical prefactors. In many definitions, an additional prefactor of $\frac{1}{2}$ is used, which results from $\hbar/2$ angular momentum per electron spin and setting $\hbar = 1$. With the same argument, for the HH band, sometimes a prefactor $3/2$ is used; but sometimes only a factor $\frac{1}{2}$ is used to have the same definition of $\mathbf{j}^\mu$ for electrons and holes. Furthermore, the rhs of equation (28) is sometimes multiplied by the charge e to obtain the same units for charge and for spin currents. In particular, this means that the sign of the definition of $\mathbf{j}^\mu$ may change if $e < 0$ for electrons is taken.

Next, we define the spin Hall conductivity

$$\sigma^{\rm SH} \equiv -\frac{j_y^z}{E_x} \tag{29}$$

where j_y^z is the spin current density resulting from a small applied electrical field E_x. The negative sign in equation (29) results from writing a formal similar definition for $\sigma^{\rm SH}$ as for the charge conductivity σ_{xy}; however, sometimes a definition with an opposite sign for $\sigma^{\rm SH}$ is used.

These various prefactors are only some technicality – the main question is whether defining j_k^i as in equation (28) makes sense. To describe spin transport it sounds attractive to find a scheme similar to the charge transport theory. Because of charge conservation, charge densities $\rho^{\rm c}$ and charge currents $\mathbf{j}^{\rm c}$ satisfy the continuity equation $\dot{\rho}^{\rm c} + \mathrm{div}\,\mathbf{j}^{\rm c} = 0$. For spin transport, we can consider the spin density $S_{\rm i}$ instead of $\rho^{\rm c}$. Mott's (1936) two-channel model of electron transport in ferromagnetic metals is based on independent and conserved currents of up- and down-spin electrons, and $\mathbf{S}$ and j_k^i obey a continuity equation. Definition (28) is the natural generalization of Mott's model; however, spin-orbit coupling violates spin conservation, and the continuity equation for spin densities and currents does not hold. In this chapter, we still use equation (28) as definition of the spin current, as it is widely used, but we remain aware of its limitations. Despite the fact that it cannot be directly related to spin accumulation, it is a useful model quantity to compare the effect of different spin-orbit coupling mechanisms. While the continuity equation does not hold, one can, for a concrete Hamiltonian, evaluate source terms arising on the rhs (Burkov, Núñez and MacDonald, 2004; Erlingsson, Schliemann and Loss, 2005), which is often termed as torque (Culcer *et al*., 2004).

Other definitions of spin currents have also been proposed. Zhang and Yang (2005) analyzed the current of the total angular momentum $L_z + S_z$ and argued that it vanishes for the Rashba Hamiltonian H_α in the absence of impurities (owing to the rotational invariance of H_α) and that thus the impurity scattering would determine angular momentum currents. Shi, Zhang, Xiao and Niu (2006) discussed spin currents, introducing a definition that is not proportional to our j_k^i, but is given as time-derivative of the 'spin displacement' $S_{\rm i}(\mathbf{r})\, r_k$. A somewhat related definition was used by Bryksin and Kleinert (2006), who found that such spin currents diverge when the frequency $\omega \to 0$.

4.2 Spin polarization

In experiments, the spin polarization can be detected optically (Meier and Zakharchenya, 1984). Electrically induced polarizations were inferred from measurements of the Kerr rotation, where the polarization of a linearly polarized beam of light rotates when the beam is reflected at a spin-polarized sample (Kato, Myers, Gossard and Awschalom, 2004b; Sih *et al*., 2005). Alternatively, the circular polarization of the recombination light at a p–n junction can be used to determine the initial polarization of the carriers (Wunderlich, Kaestner, Sinova and Jungwirth, 2005). Finally, the inverse effect, the photo-galvanic effect, can be observed, where a spin polarization is produced by polarized light and the induced electrical current is detected (Ganichev and Prettl, 2003).

In the bulk of a two- or three-dimensional sample, spin polarizations arise because an electrical field shifts the Fermi sea; $\langle \mathbf{k} \rangle = e\mathbf{E}\tau/\hbar$ for small E and with transport lifetime τ. This implies that owing to intrinsic terms, there is on average a finite spin-orbit field, $\langle \mathbf{b}(\mathbf{k}) \rangle$. This leads to a bulk spin polarization, which, in simple cases, is aligned along $\langle \mathbf{b} \rangle$ (Ivchenko and Pikus, 1978; Vas'ko and Prima, 1979; Levitov, Nazarov and Eliashberg, 1985; Edelstein, 1990; Aronov, Lyanda-Geller and Pikus, 1991). Such a polarization was observed experimentally in two-dimensional GaAs hole systems: Silov *et al*. (2004) used a (001) surface and detected the polarization of the photoluminescense from the side of the cleaved sample, while Ganichev *et al*. (2006) used samples of low crystallographic symmetry and detected the polarization along the growth direction. Furthermore, in the presence of anisotropic scattering (see Section 3.4), a magnetic field $\mathbf{B}$ can lead to polarization perpendicular to both $\langle \mathbf{b} \rangle$ and $\mathbf{B}$ (Engel, Rashba and Halperin, 2007) – such a perpendicular polarization was already observed by Kato, Myers, Gossard and Awschalom (2004a).

4.3 Spin currents in bulk

The bulk spin current j_k^i was analyzed for many different spin-orbit Hamiltonians. For a two-dimensional electron system, the intrinsic effect of the Rashba coupling H_α lead to some debate. Because j_k^i is invariant under time reversal, it is allowed to be finite in equilibrium. Indeed, such equilibrium spin currents are predicted theoretically; however, they are of order α^3 and usually small (Rashba, 2003).

Now we discuss bulk spin currents driven by an external electrical field for systems with either intrinsic or extrinsic spin-orbit interaction. We do not discuss the more complicated case when both terms are present.

When an electrical field is applied and the electrons are accelerated, the precession described in Section 3.1 was considered. Because the initial spin density for a given direction of $\mathbf{k}$ is proportional to α, but the nonadiabatic correction is proportional to $1/\alpha$, the spin-orbit coupling constant cancels. Initially, it was believed that a small concentration of impurities has no effect and a 'universal' spin Hall conductivity $\sigma^{\mathrm{SH}} = e/4\pi\hbar$ was predicted (Sinova *et al*., 2004). However, it turns out that when the impurities are properly taken into account, the vertex correction cancels the bubble term, see Figure 3. Thus, the dc conductivity σ^{SH} vanishes (Inoue, Bauer and Molenkamp, 2004; Raimondi and Schwab, 2005),

$$\sigma^{\mathrm{SH}} = 0 \tag{30}$$

which was confirmed in numerical calculations (Sheng, Sheng, Weng and Haldane, 2005). Only when the ac conductivity $\sigma^{\mathrm{SH}}(\omega)$ is considered, in the regime $1/\tau \ll \omega \ll b/\hbar$ the universal value is recovered (Mishchenko, Shytov and Halperin, 2004).

That there are no bulk spin Hall currents can be understood by the following argument given by Dimitrova (2005). Using the Heisenberg equation and for parabolic bands, one finds the identity $\mathrm{d}\sigma_y/\mathrm{d}t = -(m\alpha/\hbar^2)(\sigma_z v_y + v_y \sigma_z)$ for single-particle operators (Burkov, Núñez and MacDonald, 2004; Erlingsson, Schliemann and Loss, 2005). For a homogeneous system, one then takes the expectation value of this identity and finds that $j_y^z \propto \mathrm{d}S_z/\mathrm{d}t$. When we consider dc properties, we must assume that the system is in a stationary state (i.e., we need impurity scattering). Then, the spin polarization S_z is constant and thus $j_y^z = 0$. These arguments, as well as spin current cancellation in a magnetic field in the absence of scatterers (Rashba, 2004) show that the cancellation is an intrinsic property of the free electron Hamiltonian H_α and is not related to any specific property of the scatterers.

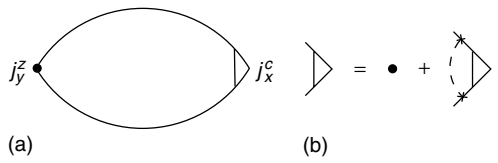

Figure 3. Diagram for spin Hall conductivity. The Kubo formula for σ^{SH} is proportional to $\mathrm{Tr}\,\langle\langle j_y^z G_{\mathrm{R}} j_x^c G_{\mathrm{A}} \rangle\rangle$, with charge current operator j_x^c and retarded and advanced Green's functions $G_{\mathrm{R/A}}$, and where $\langle\langle \cdot \rangle\rangle$ includes averaging over impurity configuration. In lowest order in $1/k_{\mathrm{F}}\ell$, we can neglect crossed impurity lines and σ^{SH} is given by the diagram shown in (a). Here, the full lines symbolize the renormalized Green's functions including self-energy. In (b), the vertex renormalization due to impurity scatterings (connected by dashed line) is defined recursively. When only the first term of (b) is taken, we get the bubble contribution to σ^{SH}; when all terms are summed, this leads to the additional (ladder) vertex correction.

Furthermore, Chalaev and Loss (2005) find that the weak localization contribution to j_y^z vanishes, and show more generally that j_y^z vanishes even if both H_α and H_β are present. Grimaldi, Cappelluti and Marsiglio (2006) find vanishing j_y^z for arbitrary values of $\alpha k_F/E_F$.

This cancellation is special to k-linear spin-orbit interaction (for nonparabolic bands, there can be a small finite contribution, proportional to α^2 (Krotkov and Das Sarma, 2006)). For example, for two-dimensional hole systems, the coupling $H_{\alpha,\mathrm{h}}$ is cubic in k (equation (11)). Then, if isotropic scattering is assumed, the vertex correction vanishes, and a 'universal' value $\sigma^{\mathrm{SH}} = 3e/4\pi\hbar$ is found in the clean limit $b\tau \gg \hbar$ (Murakami, 2004; Schliemann and Loss, 2005). Quite generally, for a 2D system where the spin-orbit field $\mathbf{b}(\mathbf{k})$ winds $N \neq 1$ times around a circle in the xy plane when $\mathbf{k}$ moves once around the Fermi circle (i.e., $N = 3$ for $H_{\alpha,\mathrm{h}}$), a universal value

$$\sigma^{\mathrm{SH}} = \frac{eN}{4\pi\hbar} \tag{31}$$

is found in the clean limit and for isotropic scattering (Shytov, Mishchenko, Engel and Halperin, 2006; Khaetskii, 2006).

Also for the k^3-Dresselhaus couplings, $H_{\mathrm{D,\,3d}}$ and $H_{\mathrm{D,\,2d}}$ (equations (8) and (9)), the vertex corrections vanish for isotropic scattering. This leads to a finite spin Hall conductivity for two-dimensional systems when $H_{\mathrm{D,\,2d}}$ is included (Mal'shukov and Chao, 2005). Similarly, σ^{SH} is finite for $H_{\mathrm{D,\,3d}}$ (Bernevig and Zhang, 2004).

The results cited above are only valid for isotropic scattering, except equation (30), which holds more generally. Recently, more general descriptions using kinetic equation (cf. Section 3.4) allowed to include arbitrary angular dependence of impurity scattering (Shytov, Mishchenko, Engel and Halperin, 2006; Khaetskii, 2006). It turns out that σ^{SH} significantly depends on the shape of the scattering potential and does not reduce to a simple form, in general. For example, in the clean limit $b\tau \gg \hbar$ and in the regime of small angle scattering (but still for a typical momentum transfer $q > b/v_F$, i.e., not too small angles), one finds

$$\sigma^{\mathrm{SH}} = -\frac{eN}{2\pi\hbar}\left(\frac{N^2-1}{N^2+1}\right)(\tilde{N} - \zeta - 2) \tag{32}$$

where ζ describes the nonparobalicity of the band, $v_\epsilon \propto k_\epsilon^{1+\zeta}$, and for $|\mathbf{b}| \propto k^{\tilde{N}}$ (Shytov, Mishchenko, Engel and Halperin, 2006). For example, taking $\zeta = 0$ and $H_{\alpha,\mathrm{h}}$, with $N = \tilde{N} = 3$, we see that the sign of σ^{SH} in equation (32) is *opposite* to the case of isotropic scattering (equation (31)). Similarly, Liu and Lei (2005) found in a numerical study of system with spin-orbit coupling $H_{\alpha,\mathrm{h}}$ that σ^{SH} strongly depends on the type of the scattering potential. Therefore, the spin Hall conductivity is not a universal quantity, as its numerical prefactor and its sign depend on sample parameters. On the other hand, for clean systems with $N \neq 1$, the order of magnitude is consistently $\left|\sigma^{\mathrm{SH}}\right| \sim e/4\pi\hbar$.

The above results are valid for weak spin-orbit coupling, $k_\alpha \ll k_F$. Conversely, there are also materials with strong spin-orbit coupling, as it was recently found in Bi/Ag (111) and Pb/Ag (111) surface alloys (Ast *et al.*, 2007). This motivated Grimaldi, Cappelluti and Marsiglio (2006) to generalize the theory, however, relying on an extensive numerical procedure.

The extrinsic contribution $H_{\mathrm{ext,\,e}}$ for electrons also leads to spin currents (D'yakonov and Perel', 1971; Hirsch, 1999). These currents are often evaluated only for isotropic impurity scattering (Zhang, 2000; Shchelushkin and Brataas, 2005). Assuming absence of intrinsic spin-orbit interaction, for arbitrary angular dependence of scattering, the extrinsic spin Hall conductivity equals (Engel, Halperin and Rashba, 2005)

$$\sigma^{\mathrm{SH}} = -\frac{\gamma}{2e}\sigma_{xx} + 2n\lambda\frac{e}{\hbar} \tag{33}$$

where the first term is due to skew scattering (see Section 3.2). The second term is due to the side-jump mechanism (Section 3.3); as this mechanism goes beyond transport equation, this term has to be evaluated separately. Here, σ_{xx} is the electrical conductivity and we defined the transport skewness

$$\gamma = \frac{\int \mathrm{d}\Omega\, I(\vartheta) S(\vartheta) \sin\vartheta}{\int \mathrm{d}\Omega\, I(\vartheta)(1-\cos\vartheta)} \tag{34}$$

that depends on the structure of the scattering center and on the Fermi energy, and I, S are defined below in equation (21). For screened Coulomb scatterers, equation (33) can be evaluated without any free parameters (Engel, Halperin and Rashba, 2005) and the resulting absolute value of spin current is in quantitative agreement (within error bars) with the observation by Kato, Myers, Gossard and Awschalom (2004b) in GaAs and seems comparable with the data by Stern *et al.* (2006) in ZnSe – implying that the observed spin currents are due to the extrinsic effect. Note that in equation (33) the skew scattering and the side-jump contributions have opposite signs. The skew-scattering term dominates in standard transport theory where one expands in $\hbar/E\tau$ where E is a typical electron energy; however, for dirty samples both terms can be of comparable magnitude. Stern *et al.* (2006) found that the measured σ^{SH} in ZnSe has the sign of the skew-scattering contribution and that the same is likely to be the case for the σ^{SH} observed by Kato, Myers, Gossard and Awschalom (2004b). Finally, assuming short-range scatterers, Tse and Das Sarma (2006a) found the

same order of magnitude for extrinsic spin currents. However; later they concluded that intrinsic spin-orbit coupling can cancel skew-scattering and reduce side-jump contributions to σ^{SH} (Tse and Das Sarma, 2006b).

Remarkably, despite the fact that the side-jump term in equation (33) was derived by including electron dynamics during the scattering event, it does not contain any factors related to the scattering probability – it only depends on the coupling constant λ, which is an intrinsic property of the material and is directly related to a Berry connection through the spin-orbit contribution to the operator of electron coordinate, cf. Section 2.6. Thus, while in this review and commonly in the literature the side-jump contribution is considered as extrinsic, it is clear that the distinction between intrinsic and extrinsic is somewhat arbitrary for this contribution.

4.4 Anomalous Hall effect and its relation to spin Hall effect

In the anomalous Hall effect (AHE), equilibrium polarization of a ferromagnet combined with spin-orbit interaction leads to electrical Hall currents transverse to an applied field. The theory of AHE has a long history and reveals many problems typical of spin transport in media with spin-orbit coupling, including the competing mechanisms of spin-orbit scattering by impurities and the role of intrinsic spin precession; for reviews see (Nozières and Lewiner, 1973; Crépieux and Bruno, 2001; Nagaosa, 2006). For noninteracting electrons and negligible spin relaxation, AHE and SHE are closely related; this is true for extrinsic spin-orbit interaction because λ is small and spin relaxation is of order λ^2 (Elliott, 1954; Yafet, 1963). In the SHE, we can decompose the spin currents $\mathbf{j}^{\mu}$ as a difference in particle currents of two spin species with polarizations $\pm\hat{\boldsymbol{\varepsilon}}_{\mu}$. Regarding these species separately, each carries the anomalous Hall current $\mathbf{J}^{\uparrow,\downarrow}_{\mathrm{AH}}$ of a system with spins fully aligned along the $\pm\hat{\boldsymbol{\varepsilon}}_{\mu}$ direction and with density $n_{\mathrm{AH}} = \frac{1}{2}n$, because we consider the SHE in nonmagnetic media, where electrons are unpolarized in equilibrium. We can express the spin Hall current as (Engel, Halperin and Rashba, 2005)

$$\mathbf{j}^{\mu}_{\mathrm{SH}} = \mathrm{e}^{-1}\left(\mathbf{J}^{\uparrow}_{\mathrm{AH}} - \mathbf{J}^{\downarrow}_{\mathrm{AH}}\right) \tag{35}$$

This relation allows to make use of the extensive literature on the AHE to gain further insights into mechanisms of the SHE, at least on its extrinsic part.

4.5 Spin accumulation and transport at boundaries

For only extrinsic spin-orbit coupling, because the spin relaxation is negligible for small λ, the spin is almost a conserved quantity and thus spin density and spin current satisfy a continuity equation with a small relaxation term. In this case, bulk spin currents will produce a spin polarization at the edge of the sample, that is, spin currents and spin accumulation are directly related (D'yakonov and Perel', 1971; Hirsch, 1999; Zhang, 2000). The polarization at a $y = 0$ edge is $S_z = (\hbar/2)\, s_z = (\hbar/2)\sqrt{\tau_{\mathrm{s}}/D_{\mathrm{s}}}\, j^z_y$, with spin-relaxation time τ_{s} and spin-diffusion coefficient D_{s} (which is identical to the electron diffusion coefficient D in the absence of electron–electron interaction).

For intrinsic spin-orbit interaction, it is not clear whether any general relation exists between spin accumulation and bulk spin currents, but spin accumulation can be studied directly. We discuss here the situation of a semi-infinite two-dimensional electron system, with Rashba coupling, located in the upper half-plane ($y > 0$). We assume a uniform applied electric field parallel to the x axis, and we consider the diffusive limit, where the spin diffusion length is large compared to the mean free path, so equations (25) and (26) apply far from the boundary. The spin density near the edge will depend on the boundary conditions for the diffusion equations at $y = 0$, and these will depend, in turn, on the boundary conditions of the microscopic Hamiltonian, as discussed in the various articles cited in the last paragraph of Section 3.5.

In the case of an ideal reflecting boundary, the spin density $\mathbf{s}(y)$ is found to be constant, and the same as in the bulk, right up to the edge (Bleibaum, 2006). Thus, one finds $s_z = 0$, while s_y has a value proportional to the charge current and to the Rashba coupling constant α. By contrast, if there is strong spin-orbit scattering at the boundary, all components of $\mathbf{s}$ should vanish there. In this case, the coupled diffusion equations predict that for $y > 0$, there will be *nonzero* values of both s_z and s_y, with oscillating behavior, in a region near the edge whose width is of the order of spin-precession length $k_{\alpha}^{-1} = \hbar^2/m\alpha$, which is about the Dyakonov–Perel spin-diffusion length $\sqrt{D_s \tau_s}$ (Rashba, 2006).

What happens if the boundary at $y = 0$ is partially or completely transmitting and there is a second conductor in the region $y < 0$ which has no spin orbit coupling? As noted by Adagideli and Bauer (2005), one should expect, in general, to find nonzero oscillatory values of both s_z and s_y in the Rashba conductor near the boundary, and injection of spin into the non-spin-orbit material. However, it was found by Tserkovnyak, Halperin, Kovalev and Brataas (2006) that this actually will not happen in the simplest case that one might consider: a boundary between a pair of two-dimensional systems with identical properties except for different values of α. There will quite generally be a discontinuity in the spin densities at a lateral boundary between systems with different Rashba coupling. If the electron mobility is a constant across the boundary, the discontinuity turns out to be equal to the

difference between the bulk spin densities of the systems. Then, on each side of the boundary one finds $s_z = 0$, while s_y is the same as the respective bulk value. There will thus be no spin injection if the second two-dimensional electron system has $\alpha = 0$.

Mal'shukov, Wang, Chu and Chao (2005) have argued that there should be spin accumulation near a reflecting edge, in the diffusive case, when the cubic Dresselhaus coupling $H_{\mathrm{D,2d}}$ is important. In the opposite limit of ballistic transport and near a sharp specular edge, Usaj and Balseiro (2005) have found spin magnetization due to H_α that oscillates rapidly with a period of k_{F}^{-1} and shows beating on a length scale of k_α^{-1}.

There are also numerical approaches analyzing the edge spin accumulation. Nomura *et al*. (2005) simulated a two-dimensional hole system, using the coupling $H_{\alpha,\mathrm{h}}$ (equation (11)). They found a spin accumulation that was consistent with the experiments by Wunderlich, Kaestner, Sinova and Jungwirth (2005).

4.6 Mesoscopic systems and spin interferometers

So far we have not considered interference effects – for example, in Section 3.4, we used an expansion in lowest order $1/k_{\mathrm{F}}\ell$ which does not include interference between electron propagation paths that follow different trajectories. To include such coherent effects in systems with impurities, one needs to consider the next order in $1/k_{\mathrm{F}}\ell$: the weak localization corrections. Alternatively, one can consider clean systems that are ballistic on length scales of the device. Spin interference effects in mesoscopic systems open up a new set of technical possibilities, for example, in rings or ringlike arrays with spin-orbit interaction, one can use Berry phase and Aharonov–Casher phase effects to study a variety of phenomena. In the presence of an applied magnetic field, spin-orbit effects can modify the Aharonov–Bohm or Altshuler–Aronov–Spivak oscillations in the electrical conductance. For theoretical discussions, see (Aronov and Lyanda-Geller, 1993; Bulgakov *et al*., 1999; Engel and Loss, 2000; Frustaglia, Hentschel and Richter, 2001; Koga, Nitta and van Veenhuizen, 2004; Aeberhard, Wakabayashi and Sigrist, 2005). For experimental results, see (Morpurgo *et al*., 1998; Yau, Poortere and Shayegan, 2002; Yang, Yang and Lyanda-Geller, 2004; Koga, Sekine and Nitta, 2006; Koenig *et al*., 2006; Bagraev *et al*., 2006).

For practical applications, it is not only important to generate nonequilibrium spin polarization in media with spin-orbit coupling, but also inject spin currents produced by such populations into 'normal' conductors, that is, conductors with negligible spin-orbit coupling. In normal conductors, spin is conserved and spin currents are well defined. Spin injection can be achieved using spin-orbit coupling, even in devices without magnetic fields and without ferromagnetic components. Proposals for such devices, in the mesoscopic regime, have been made by (Kiselev and Kim, 2003; Shekhter, Khodas and Finkel'stein, 2005; Souma and Nikolić, 2005; Eto, Hayashi and Kurotani, 2005; Silvestrov and Mishchenko, 2006).

Generally, spin interference devices make use of the intrinsic and extrinsic spin-orbit couplings presented in Section 2 and the spin-transport mechanisms discussed in Section 3 are important. However, we do not present more concrete descriptions of interference effects or details of microscopic structures; this could be done by solving the Schrödinger equation analytically, by simulating it numerically, or by using weak localization calculations. On the other hand, we can assess the length scales on which spin precession effects are expected: both diffusion equation (Section 3.5) and its solution near boundaries (Section 4.5) indicate spin-precession length $\ell_\alpha = 1/k_\alpha$ as a characteristic length for spin distributions. Furthermore, for clean systems, responses to an inhomogeneous field diverge at the wave vector $q = 2k_\alpha$ of the field (Rashba, 2005). This 'breakdown' suggests the length ℓ_α as an optimal size for achieving large spin polarizations. For a more generic Hamiltonian H_{int}, this scale can be estimated as $\ell_{\mathrm{eff}} \sim \hbar^2 k_{\mathrm{F}}/m\,|\mathbf{b}|$, establishing a 'mesoscopic' scale at which one can expect largest static spin responses to electric fields. Because ℓ_{eff} is also of the order of the Dyakonov–Perel spin-diffusion length, this estimate seems applicable both to the ballistic and diffusive regimes.

5 SPIN HALL EFFECT DUE TO EDGE STATES IN INSULATORS

In the previous parts of Section 4, we discussed spin currents j_y^z driven by electric field E_x, their relevance to spin transport and spin accumulation, and also the techniques for calculating conductivities σ^{SH} (equation (29)). Even when these nondiagonal components of the tensor j_j^i were not directly influenced by dissipation, they were calculated for ordinary metallic conductors whose longitudinal electric conductivity σ_{xx} was controlled by electron scattering, hence, electron transport in the bulk was dissipative. More recently, Murakami, Nagaosa and Zhang (2004) proposed that some centrosymmetric 3D systems possess properties of 'spin insulators'. These are media with gapped electron spectra and zero bulk electrical conductivities σ_{xx} but finite and dissipationless spin conductivities σ^{SH}.

The basic idea is as follows. A set of electron bands that in absence of SO coupling belongs to orbital momentum $\mathbf{L}$, in presence of SO coupling is described by the total angular

momentum $\mathbf{J} = \mathbf{L} + \mathbf{S}$. When some of the bands belonging to the $\mathbf{J}$ multiplet are filled, while different bands of the same multiplet are empty and are separated from the filled bands by a gap, all filled bands contribute to spin current. Uniaxially strained zero-gap semiconductors α-Sn and HgTe, and narrow-gap semiconductors of PbTe type were proposed as model systems. Spin conductivity σ^{SH} is large in these materials: it is about $e/\hbar a$ in 3D, a being the lattice constant. In 2D, σ^{SH} is quantized when the Fermi level is inside the gap (Qi, Wu and Zhang, 2006; Onoda and Nagaosa, 2005). However, for reasons similar to those discussed in Section 4.1, the relation of this σ^{SH} to spin transport is not obvious and was already questioned (Kane and Mele, 2005a; 2005b).

A different concept of spin transport in an insulating phase has been developed by Kane and Mele as applied to graphene (Kane and Mele, 2005a; 2005b). It is based on the Haldane model of quantum Hall effect (QHE) with spinless fermions under the conditions of zero total magnetic flux across the unit cell (Haldane, 1988). It has been emphasized (Onoda and Nagaosa, 2005; Kane and Mele, 2005a) that this model differs fundamentally from the model by Murakami, Nagaosa and Zhang (2004), in particular, in the properties of edge channels. Their crucial role for the QHE has been clarified by Halperin (1982), and they play a similar role in the physics of spin Hall effect in graphene. In what follows, we consider properties of graphene in more detail. The graphene model is not only of conceptual interest but is also attractive because of the very recent experimental achievements in measuring electron transport in graphene (Novoselov *et al.*, 2004; Zhang, Tan, Stormer and Kim, 2005).

Graphene is a monoatomic layer of graphite. Its honeycomb 2D lattice is shown in Figure 4. The elementary cell includes two atoms shown as A and B. The phase diagram of

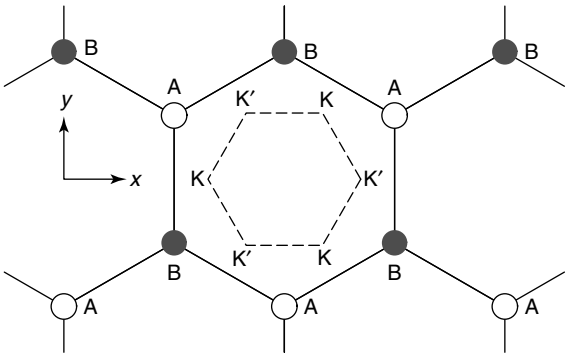

Figure 4. Schematics of honeycomb lattice of graphene. The hexagon in the center is an elementary cell containing two carbon atoms that belong to two sublattices. Atoms of these sublattices are marked as A and B and are shown by empty and filled circles, respectively. Brillouin zone is shown by a dashed line. K and K′ indicate nonequivalent corners of the zone where the gap opens.

graphene can be understood from the tight-binding Hamiltonian (Kane and Mele, 2005b)

$$H = t\sum_{\langle ij\rangle} c_i^+ c_j + \frac{2i}{\sqrt{3}}\lambda_{\mathrm{SO}}\sum_{\langle\langle ij\rangle\rangle} \nu_{ij} c_i^+ \sigma_z c_j + i\lambda_{\mathrm{R}}\sum_{\langle ij\rangle} c_i^+ (\boldsymbol{\sigma}\times\hat{\mathbf{d}}_{ij})_z c_j + \lambda_{\mathrm{v}}\sum_i \xi_i c_i^+ c_i \quad (36)$$

where c_{i} are annihilation operators at lattice cites i, spin indices in them being suppressed. The first term is the nearest neighbor hopping term between two sublattices. For the following, of the critical importance is the second term with $\nu_{ij} = (2/\sqrt{3})(\hat{\mathbf{d}}_1 \times \hat{\mathbf{d}}_2)_z = \pm 1$ that describes second neighbor hopping. Here $\hat{\mathbf{d}}_1$ and $\hat{\mathbf{d}}_2$ are unit vectors along two bonds that an electron traverses when going from the site j to the site i. The cross product of $\hat{\mathbf{d}}_1$ and $\hat{\mathbf{d}}_2$ produces a screw that in the Haldane model of spinless fermions couples them to inhomogeneous magnetic flux, while in the present model it couples the orbital motion of an electron to Pauli matrix σ_z. Hence, λ_{SO} is a coupling constant of a mirror symmetric, $z \to -z$, spin-orbit interaction. The third term is a nearest neighbor Rashba term, $\hat{\mathbf{d}}_{ij}$ being a unit vector in the direction connecting i and j nodes. It explicitly violates $z \to -z$ symmetry and originates from the coupling to the substrate or from an external electric field. The fourth term is a staggered sublattice potential with ξ_{i} taking values $\xi_{\mathrm{i}} = \pm 1$ for A and B lattice sites. It vanishes for graphene but would be present for a similar boron nitride (BN) film. Including this term is a clue for explaining the difference between the 'quantum spin Hall' (QSH) phase and a usual insulator (Kane and Mele, 2005a; 2005b).

The remarkable spin properties of graphene are seen from the one-dimensional projection of its energy spectrum, Figure 5, found by solving the Hamiltonian of equation (36) in the geometry of a strip with finite extent in the y direction (defined in Figure 4), that is, having 'zigzag' edges aligned along the x direction. The spectrum comprises four energy bands, of which the two lower bands are occupied; each bulk band is twofold spin degenerate. Narrow gaps at K and K′ open because of $\lambda_{\mathrm{SO}}, \lambda_{\mathrm{v}} \neq 0$ – for $\lambda_{\mathrm{SO}}, \lambda_{\mathrm{v}} = 0$, electrons possess a k-linear spectrum of Dirac fermions, $\varepsilon(k) = \hbar c^* k$. In addition to bulk states, there are edge states connecting K and K′ bulk continua. Their topology in the panels (a) and (b) is rather different.

In the panel (a) drawn for a small λ_{v}, edge states traverse the gap. For each edge of the strip, there are two such states. They are Kramers conjugate and propagate in opposite directions. This behavior reflects unusual cross-symmetry of bulk states that manifests itself in the opposite signs of the gap function at K and K′ points. The small-λ_{v} phase has been dubbed as QSH phase by Kane and Mele (2005a). It is the

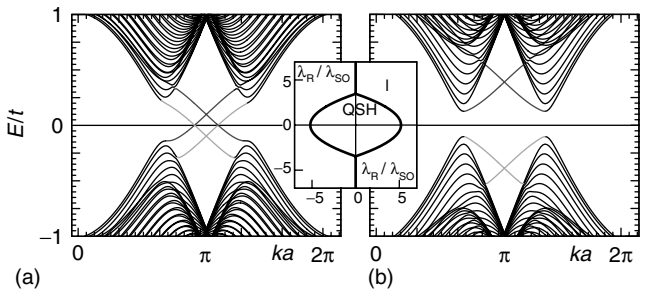

Figure 5. Energy bands of a one-dimensional strip of graphene with 'zigzag' edges, that is, the strip has finite extent along the y direction shown in Figure 4. Narrow gaps in the bulk spectrum are achieved at the K- and K′ vertices of the Brillouin zone. Branches of the spectrum originating from the edges of bulk continua show energies of edge states. Edge states at a given edge of the strip cross at $ka = \pi$, a being the lattice spacing. (a) QSH phase for $\lambda_v = 0.1t$; edge states at a given edge of the strip cross at $ka = \pi$, a being the lattice spacing. (b) A normal insulating phase for $\lambda_v = 0.4t$. In both cases, $\lambda_{SO} = 0.06t$ and $\lambda_R = 0.05t$. The inset shows the phase diagram in the λ_v–λ_R plane for $0 < \lambda_{SO} \ll t$. (Reproduced from C.L. Kane *et al*., 2005, with permission from the American Physical Society. © 2005.)

distinctive property of this phase that at any energy inside the gap there is one pair of edge modes (more generally, an odd number of such pairs).

When $\lambda_R = 0$, σ_z is conserved, and the pattern of dissipationless spin transport become especially simple. Each of independent subsystems of $\sigma_z = \uparrow$ and $\sigma_z = \downarrow$ electrons is equivalent to Haldane spinless fermions (Haldane, 1988). One pair of such 'spin filtered' states propagates along each edge. The states with opposite σ_z polarizations propagate in opposite directions. Because they form a Kramers doublet, potential backscattering is forbidden and transport is dissipationless. This model predicts two-terminal electric conductivity $G = 2e^2/h$. Propagation of charge current through edge states results in antisymmetric spin accumulation at these edges. In four-terminal geometry, spin currents flow between adjacent contacts, and related spin conductances are quantized; when normalized on a number of transported spins, $G^s = \pm e/2\pi\hbar$. For $\lambda_R \neq 0$, however, σ_z is not conserved. Nevertheless, spin currents persist (if λ_R is small, see the following text) but they are no longer exactly quantized. An early argument that the spin Hall conductance can be quantized was given by Froehlich, Studer and Thiran (1995) when considering incompressible 2D systems.

Panel (b) of Figure 5, drawn for a larger staggered potential λ_v, shows properties of a normal narrow-gap insulator. The gap function has the same sign at K and K′, as a result, one pair of edge states runs between two conduction-band valleys and the second pair between two valence band valleys. For some boundary conditions at the strip edges, edge states can penetrate the gap. However, there is always an even number of Kramers conjugate pairs of edge states at any given energy inside the gap, hence, backscattering is no longer forbidden. Therefore, it is the topology of edge states that defines the difference between the QSH and insulating phases in a simple and concise form.

The QSH phase is formed due to the bulk spin-orbit coupling λ_{SO}. Increasing asymmetric λ_R or staggered λ_v potentials destroy it when they become large enough. A phase diagram of the competing phases, QSH phase, and a normal insulator, is shown in the inset to Figure 5. The QSH phase exists inside an ovaloid in the λ_v/λ_{SO}–λ_R/λ_{SO} plane. Outside it, graphene shows properties of a normal narrow-gap insulator.

Another factor suppressing the gap and spin conductivity is electron scattering in the bulk. Its effect has been investigated numerically by Sheng, Sheng, Ting and Haldane (2005) for a four-probe spin Hall setup using the Landauer–Büttiker formula (Landauer, 1988; Büttiker, 1988); their spin conductivity σ^{SH} describes real spin transport. Disorder was modeled as $\sum_i \epsilon_i c_i^+ c_i$ with ϵ_i randomly distributed in the interval $[-W/2, W/2]$. They found that σ^{SH} remains within a few percent of its quantized value when $W < t$ and the Fermi level stays inside the gap; and σ^{SH} drops fast with increasing W for $W \gtrsim 1.5t$. Under the same conditions, σ^{SH} remains stable for $\lambda_R \lesssim 0.2t$. These results allow to establish the parameter range inside which edge spin channels remain robust and carry dissipationless and nearly quantized spin currents. Inside this range, there exist close analogy between QSH and QHE systems.

Currently, there is no direct experimental indication of the spin gap in graphene. A crude theoretical estimate of it by Kane and Mele (2005a) results in the gap $2\Delta_{SO} \sim 2.4\,\mathrm{K}$ which is in a reasonable agreement with different data (Brandt, Chudinov and Ponomarev, 1988). However, more recent calculations indicate that the actual value of Δ_{SO} is considerably smaller. Meantime, estimates of $\hbar/\tau$ based on transport data result in $\hbar/\tau \gtrsim 25\,\mathrm{K}$ for typical mobilities of $\mu \approx 10\,000\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$, τ being the momentum relaxation time. Comparison of these data can easily explain suppression of spin-polarized transport through edge channels by disorder in the samples that are currently available. An independent mechanism of suppression is the λ_R constant that develops when electron concentration is controlled by a gate, and the ratio λ_R/λ_{SO} is unknown. Unfortunately, all estimates are crude because electron transport in graphene is still not understood. Novoselov *et al*. (2005) recently reported the minimum metallic conductivity $4e^2/h$ when the Fermi level passes through the conic point of the spectrum; it is nearly independent of the mobility μ. A nonuniversal and even larger conductivity of about $6e^2/h$ was reported by (Zhang, Tan, Stormer and Kim, 2005). The closest theoretical value $2e^2/h$ comes from the spin channel model (Kane and Mele,

2005a), followed by $4e^2/\pi h$ and $2e^2/\pi h$ found from different models of the bulk transport of Dirac fermions (Ziegler, 1998; Shon and Ando, 1998). Because there exists a region of parameter values where spin transport through edge channels is robust, honeycomb lattices lithographically produced from semiconductors with strong spin-orbit coupling may also be of interest (Zheng and Ando, 2002).

Abanin, Lee and Levitov (2006) argued that in the QHE regime, the exchange-enhanced gap for chiral edge modes, originating from Zeeman splitting, may be as large as 100 K. Another system where edge spin channels may play a role was proposed by Bernevig and Zhang (2006); it includes parabolic confinement in conjunction with inhomogeneous shear deformation. More recently, Fu and Kane (2006) proposed $Bi_{1-x}Sb_x$ semiconductor alloys and α-Sn and HgTe under uniaxial strain as materials that satisfy the necessary symmetry requirements for the QSH phase and that are expected to have a large Δ_{SO}. Independently, Bernevig, Hughesm, and Zhang (2006) showed that HgTe/CdTe quantum wells are also good candidates for the QSH phase.

NOTES

[1] This is reminiscent of the definition of an 'intrinsic semiconductor', which is so pure that (at a sufficiently high temperature) the impurity contribution to the carrier density is negligible. The conductivity of such a sample is known as *intrinsic* conductivity (again, a finite transport lifetime τ is required to make the conductivity well defined). At lower temperatures, the carrier density mainly results from the impurities and now one refers to *extrinsic* properties.

Manipulation of Spins and Coherence in Semiconductors

Nathaniel P. Stern, Jesse Berezovsky, Sayantani Ghosh and David D. Awschalom

University of California, Santa Barbara, CA, USA

1 INTRODUCTION

The physics of spins in semiconductors was first seriously explored in pioneering theoretical and experimental work in the 1960s (Meier and Zakharechenya, 1984). Since then, advances in materials science and semiconductor processing technology have opened up vast new territories of conceptual space, rich in fascinating spin-related phenomena. This chapter highlights recent measurements involving spin coherence in semiconductor structures.

There is currently significant interest in the potential applications of spins in semiconductors (referred to as *spintronics* (Wolf *et al*., 2001)). Existing semiconductor devices rely solely on the charge of the electron and the orbital part of the electron wave function. However, it is becoming evident that the electron spin, previously ignored, can also be manipulated and detected in a number of ways in semiconductor systems. Novel interactions between spins and light have been explored, allowing for all-optical control of spin coherence (Gupta, Knobel, Samarth and Awschalom, 2001; Hübner *et al*., 2003; Gurudev Dutt *et al*., 2006); structures can be engineered for spin manipulation through the introduction of magnetic dopants; and significantly, all-electrical methods for spin generation, manipulation, and detection have been developed that do not require magnetic fields or magnetic materials (Kato, Myers, Gossard and Awschalom, 2004a,b,c; 2003, Hanbicki, van 't Erve and Magno, 2003; Lou *et al*., 2006). To date, no commercially viable device has been demonstrated in the field of semiconductor spintronics, but as we gain understanding of the underlying physical phenomena, it seems increasingly evident that God would not have created such an extraordinary garden if man were not meant to enjoy its bounty.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

2 COHERENT SPIN ENSEMBLES AND OPTICAL MEASUREMENT

A significant barrier to the practical use of spins in semiconductors is the ephemeral nature of the spin state – unlike charge, spin is not a conserved quantity. The average time for the loss of spin information is described by two quantities, the longitudinal spin lifetime, T_1 (also known as the *spin-flip time*), and the transverse spin lifetime T_2 (also known as

the *coherence time*). In general, T_1 refers to the time for the relative amplitudes of the spin eigenstates (e.g., spin-up and spin-down) to become scrambled and T_2 refers to the time for the relative phase of the eigenstates to be lost. In the case where many spins are measured simultaneously, inhomogeneities in the spin dynamics over the ensemble result in a reduced effective transverse spin lifetime, referred to as T_2^* .

There are several mechanisms that contribute to the decay and decoherence of spins in semiconductors. Through spin–orbit (SO) coupling in a noncentrosymmetric crystal (e.g., zinc blende, wurtzite), an electron's momentum acts as a magnetic field seen by the electron spin (Yu and Cardona, 1996). In the D'yakonov–Perel mechanism (D'yakonov and Perel, 1971a), as the electron momentum is repeatedly scattered, the electron spin state is randomized as it precesses about this fluctuating effective field. Furthermore, the SO interaction mixes the spin and momentum eigenstates, directly linking momentum scattering with spin scattering. This path to spin decoherence is known as the *Elliot–Yafet mechanism* (Elliot, 1954). These two spin-orbit mediated mechanisms show opposite dependence on the momentum scattering rate. In the Elliot–Yafet mechanism, more momentum scattering leads to more spin scattering. In contrast, as momentum scattering increases, the fluctuating effective field of the D'yakonov–Perel mechanism tends to 'cancel out', in an effect akin to motional narrowing seen in nuclear magnetic resonance (NMR) (Abragam, 1961).

Electron spins can also be flipped through interactions with other spin systems, such as through the electron–hole exchange interaction (Bir–Aronov–Pikus mechanism (Bir, Aronov and Pikus, 1976)), or through the hyperfine interaction with nuclear spins (Lampel, 1968). These mechanisms become significant when the electron wave function has significant overlap with the holes or with nuclei, respectively.

Despite the inevitability of spin decoherence, relatively long spin lifetimes have been measured in some semiconductor systems. In bulk n-type GaAs, T_2^* has been found to exceed 100 ns at low temperature (Kikkawa and Awschalom, 1998). The spin lifetime in GaAs is found to depend strongly on the donor concentration, with a maximum occurring near the metal–insulator transition owing to the changing strength of the different spin relaxation mechanisms (Dzhioev *et al*., 2002). Some II–VI semiconductors, such as ZnSe, show robust spin coherence up to room temperature (Kikkawa, Smorchkova, Samarth and Awschalom, 1997). Such materials have relatively large band gaps and small SO coupling, and therefore less spin decoherence owing to the D'yakonov–Perel or Elliot–Yafet mechanisms. Furthermore, by confining electrons within a quantum dot (QD), momentum scattering is suppressed, leading to longer spin lifetimes. T_1 times up to 0.85 ms have been measured in GaAs QDs at 300 mK in a magnetic field of 8 T (Elzerman *et al*., 2004) and 20 ms in InAs QDs at 1 K in a 4 T field (Kroutvar *et al*., 2004). A time-averaged *transverse* electron spin lifetime, T_2^*, of 16 ns has been observed in single GaAs QD (Bracker *et al*., 2005). In variants of the spin-echo technique used in NMR (Abragam, 1961), the T_2 time of InAs QDs has been measured to be ∼3 µs at 6 K (Greilich *et al*., 2006), and the singlet–triplet coherence time in a double QD structure has been found to be greater than 1 µs at 135 mK (Petta *et al*., 2005).

The selection rules governing optical transitions from the valence band to the conduction band of noncentrosymmetric crystals provide a useful means for initializing and detecting spin polarization in these materials (Meier and Zakharechenya, 1984) (see Figure 1). The conduction band minimum (the Γ-point) is twofold degenerate, corresponding to the two spin states ($S = 1/2$, $S_z = \pm 1/2$). The six states at the valence band maximum are split into the fourfold degenerate heavy holes ($J = 3/2$, $J_z = \pm 3/2$) and light holes ($J = 3/2$, $J_z = \pm 1/2$), and the doubly degenerate split-off holes ($J = 1/2$, $J_z = \pm 1/2$). The split-off band is typically sufficiently far from the heavy and light holes that split-off hole transitions can be ignored for excitation near the band edge.

A circularly polarized photon carries angular momentum of 1 $\hbar$, and thus can only drive transitions with $\Delta L_z = \pm 1$. For example, absorption of a photon with $l = 1$ can drive the transition from a heavy-hole state with $J_z = -3/2$ to an electron state with $S_z = -1/2$, or the transition from a light-hole state with $J_z = -1/2$ to an electron state with $S_z = 1/2$. Calculating the dipole transition matrix elements for these

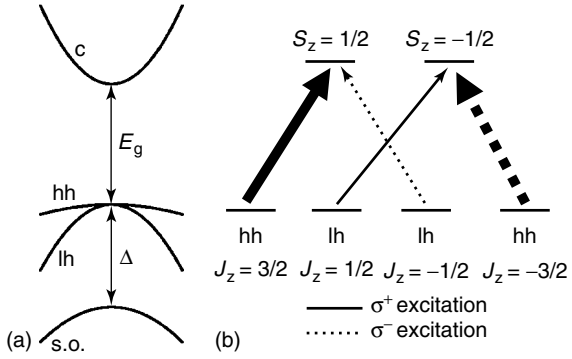

Figure 1. (a) Schematic of the band structure of a zinc-blende semiconductor, showing the conduction band (c), heavy-hole band (hh), light-hole band (lh), and split-off hole band (s.o.). Also indicated are the energy gap, E_g, and the spin-orbit splitting Δ. (b) Diagram of the four band-edge transitions and selection rules for circularly polarized light. The width of the lines indicates the strength of the transition.

two transitions, one finds that the heavy-hole transition is more likely than the light-hole transition by a factor of 3. In this way, circularly polarized optical excitation near the band edge results in the pumping of a net electron spin polarization in the conduction band.

The situation is improved further in strained crystals or with quantum confinement, which can lift the degeneracy between the heavy and light holes. In this case, transitions from only one hole band can be driven resulting in nearly 100% spin polarization.

These spin-dependent selection rules not only allow for the initialization of spin-polarized electrons and holes, but also the measurement of spin polarization. In the opposite process of optical spin pumping, when spin-polarized electrons and holes recombine radiatively, the resulting luminescence is circularly polarized. By measuring this polarization, the spin polarization at the time of the recombination can be inferred.

In a Hanle measurement (Figure 2a), spins are optically initialized using circularly polarized light perpendicular to an applied magnetic field. As the injected spins precess about this field, the steady-state spin polarization is reduced. The resulting curve of polarization versus magnetic field typically shows a Lorentzian lineshape, with width proportional to the transverse spin lifetime. The Hanle technique was used extensively in early measurements of spins in semiconductors (Meier and Zakharechenya, 1984), and have been used more recently in experiments to measure a single electron spin in a GaAs QD (Bracker *et al*., 2005) and in measurements of spins injected from a ferromagnetic metal into a semiconductor light-emitting diode (Strand *et al*., 2003).

A more direct measurement of spin polarization can be obtained through the Faraday effect (Faraday, 1846). Here, a net spin polarization in a material results in a different index of refraction for left and right circularly polarized light. Thus when linearly polarized light is transmitted through the material, the two circularly polarized components acquire a relative phase shift, yielding a rotation of the polarization of the transmitted light. The angle through which the polarization is rotated is proportional to the spin polarization along the axis of the light propagation. The same effect occurs upon reflection off the sample, in this case known as *Kerr rotation* (*KR*).

Faraday rotation (or KR) can be used to probe the steady-state spin polarization, similar to the Hanle measurement discussed in the preceding text (Figure 2b). By using Faraday rotation instead of a traditional Hanle measurement, one gains the ability to measure spins that do not undergo radiative recombination. Additionally, Faraday rotation provides spectroscopic information about the energy levels occupied by the spins through the energy-dependence of the Faraday effect (Meier and Awschalom, 2005). This measurement technique proves especially useful for spins that are not

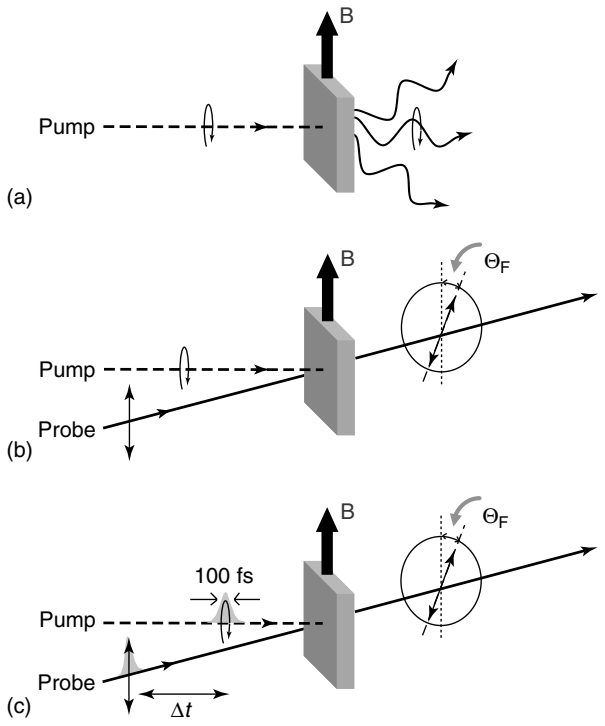

Figure 2. (a) Schematic of a Hanle measurement. Spins are injected with circularly polarized excitation, and the degree of circular polarization of the photoluminescence is measured. (b) Schematic of a DC Faraday rotation measurement. Spin polarization is measured through the rotation of a linearly polarized probe beam. (c) Schematic of a time-resolved Faraday rotation measurement. A circularly polarized pump pulse excites spins, which are probed a time Δt later through the rotation of a linearly polarized probe pulse.

optically injected. DC Faraday or KR measurements have recently been used for studying electrical spin injection and accumulation in ferromagnetic metal/nonmagnetic semiconductor heterostructures (Stephens *et al*., 2004; Crooker *et al*., 2005). Also, measurements of intrinsically generated spin polarizations through the spin Hall effect (Kato, Myers, Gossard and Awschalom, 2004c) or current-induced spin polarization (Kato, Myers, Gossard and Awschalom, 2004b) are also possible using this method.

The Faraday and Kerr effects can be used in conjunction with ultrafast optical techniques for time-resolved measurements of spin coherence in semiconductors (Awschalom *et al*., 1985; Baumberg *et al*., 1994; Östreich, Schönhammer and Sham, 1995; Crooker *et al*., 1997), (Figure 2c). In such measurements, a mode-locked Ti:Sapphire laser provides a train of pump and probe pulses with subpicosecond duration, which are both focused to a spot on the sample. The pump pulse is circularly polarized, and serves to optically inject spin-polarized electrons into the conduction band. The arrival of the probe pulse is delayed from the pump by changing

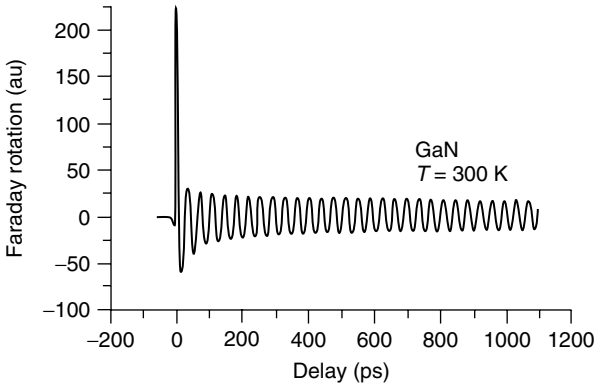

Figure 3. Coherent spin precession in GaN measured by time-resolved Faraday rotation. (Adapted from Beschoten *et al.*, 2001.)

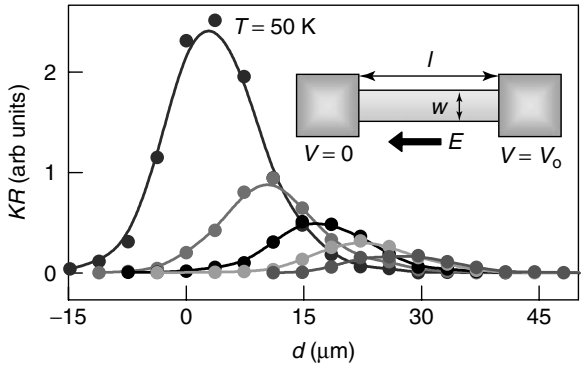

Figure 4. Schematic of the device geometry for spin drag measurements $l = 300\,\mu\text{m}$, $w = 100\,\mu\text{m}$. Spatial profiles of the optically injected spin packet, in n-type bulk ZnSe, extracted from Fourier transforms of θ_K at $E = 60\,\text{mV}\,\mu\text{m}^{-1}$ for $\Delta t = 13.1\,\text{ns}$, $\Delta t = 26.2\,\text{ns}$, $\Delta t = 39.3\,\text{ns}$, $\Delta t = 52.4\,\text{ns}$, and $\Delta t = 65.5\,\text{ns}$, in the order of decreasing amplitude. (Reprinted with permission Stern *et al.*, copyright 2006, American Physical Society.)

the optical path length of the probe. The probe is linearly polarized, and the resulting Faraday (or Kerr) rotation of the probe serves as an instantaneous measurement of the spin polarization at the moment of incidence on the sample. If the spins are initialized into a coherent superposition of spin eigenstates, the projection of the resulting dynamics along the probe direction can be observed as a function of time. For example, Figure 3 shows the coherent quantum beating between electron spin levels Zeeman-split by a transverse magnetic field in GaN at room temperature. By fitting such a curve, the transverse spin lifetime and the electron g-factor can be extracted.

3 ELECTRICAL GENERATION AND MANIPULATION OF SPIN POLARIZATION

In the previous section, we have demonstrated the ability to create and detect electron spin coherence using optical means. Here, we address the issue of using electric fields to create, manipulate, and transport spin-polarized electrons in semiconducting materials. A significant challenge in the transport of spin-polarized carriers over useful length scales and through heterointerfaces is the ability to do so without destroying the spin coherence. Spatially resolved KR allows the study of mesoscopic lateral spin transport in devices with an externally applied, in-plane electric field. In this pump-probe technique, two beams are normally incident on the sample and focused to a 15-μm spot. The KR of the probe maps the electron spin polarization as the relative separation d of the pump and probe is varied in the direction of the electric field. Figure 4 follows the optically injected spin packet as it is dragged along the channel by an electric field of $60\,\text{mV}\,\mu\text{m}^{-1}$ in the n-type ZnSe channel ($n = 5 \times 10^{16}\,\text{cm}^{-3}$). Extracting the drift velocity from the center of the spin packets allows an estimate of the spin mobility of $\mu_s = 89 \pm 14\,\text{cm}^2\,\text{V}^{-1}\text{s}^{-1}$. This is 20 times less than that measured in GaAs, where time and spatially resolved measurements show that spin lifetimes can exceed hundreds of nanoseconds, and spin packets can be transported over a hundred microns (Kikkawa and Awschalom, 1999). These lateral spin drag experiments in both II–VI and III–V semiconductors demonstrate that spin polarization can be transported over micron-scale distances in semiconductors with the application of an electric field.

The interaction between a spin magnetic moment and a magnetic field **B** gives rise to the Zeeman energy splitting and the precession of a spin about a transverse magnetic field mentioned in Section 2:

$$H_Z = \mu_B \vec{B} \cdot \overleftrightarrow{g} \cdot \vec{\sigma} \tag{1}$$

where μ_B is the Bohr magneton, $\vec{\sigma}$ is the spin operator, and $\overleftrightarrow{g}$ is the Landé g-tensor. Semiconductors allow a great amount of control of this interaction through the material-dependent g-factor (See also **Spin Engineering in Quantum Well Structures, Volume 5**). For example, spin precession can be modulated at GHz frequencies using an electric field to control the g-factor of electrons in parabolically graded heterostrcutures (Kato, Myers, Gossard and Awschalom, 2003). Conventional spin manipulation through the g-factor is limited, however, in that it still requires the application of an external magnetic field. But, the capability of manipulating electron spins in nonmagnetic semiconductors in the absence of such an external magnetic field has practical implications for spin-based quantum information processing (Loss and DiVincenzo, 1998) and spin-based electronics (Awschalom, Loss and Samarth, 2002;

Wolf *et al*., 2001). Single qubit operations require a local Hamiltonian, which is tunable within coherence times that generally do not exceed a few nanoseconds. The scaling down of devices for on-chip integration requires precise control of magnetic fields at micron-scale dimensions or even smaller. External magnetic fields are limited on both accounts – it is both difficult to create large fields in a short timescale, as well as to spatially localize a field without complicated architectures.

The SO interaction provides a unique pathway for spin manipulation through electric fields without magnetic fields or magnetic materials (Aronov, Lander-Geller and Pikus, 1991). The SO Hamiltonian, given by

$$H_{\mathrm{SO}} = \frac{\hbar}{4m_0^2c^2}[\vec{\nabla}V(\vec{r}) \times \vec{p}] \cdot \vec{\sigma} \tag{2}$$

is a consequence of relativity arising from the transformation of an electric field into a magnetic field in the frame of a moving electron. According to the form of equation 2, the electric field and orbital momentum create an effective magnetic field that acts on the spin operator in the same way as the magnetic field in equation 1. This electric field need not be a real field, but a 'quasi electric field', arising from asymmetries in the crystal field, the band gap, or strain-induced spin splitting. In this part of the chapter, we describe experiments investigating the existence of strain-induced internal magnetic field in *n*-GaAs and *n*-ZnSe and show electrical generation of spin polarization in these semiconductors through SO coupling, performed at low temperatures in GaAs (Kato, Myers, Gossard and Awschalom, 2004b) and at higher temperatures persisting to 300 K, in ZnSe (Stern *et al*., 2006).

The GaAs samples are grown by molecular-beam epitaxy (MBE) and consist of a 2-μm *n*-GaAs layer ($n = 3 \times 10^{16}\,\mathrm{cm}^{-3}$) acting as a spin probe layer at the surface and a 2-μm film of $Al_{0.4}Ga_{0.6}As$ underneath serving as a stressor/etch layer. The semi-insulating GaAs (001) substrate is removed by chemical etching in order to form a rectangular membrane with dimensions ∼100 by ∼300 μm. The processed membrane has curvature, possibly due to the larger lattice constant or the oxidation of the $Al_{0.4}Ga_{0.6}As$ layer, thereby straining the *n*-GaAs film. Ohmic contacts are evaporated on the surface in order to apply an in-plane electric field **E** along the $[1\bar{1}0]$ crystallographic direction. The in-plane strain, estimated using optical interference fringes at room temperature, is $\sim 10^{-5}$.

Electron spin dynamics is probed using the same time-resolved KR technique mentioned earlier for studying spin transport. Figure 5(a)–(d) shows the spatiotemporal evolution of a coherent electron spin packet with zero external field, under various applied E. The spin packet

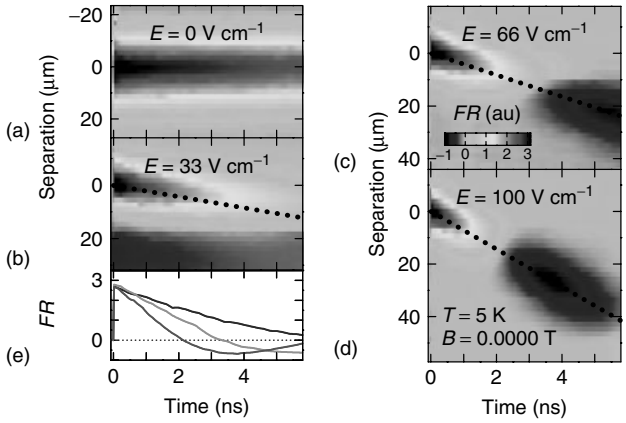

Figure 5. Spatiotemporal evolution of the photoexcited spin packet at zero magnetic field. (a)–(d) FR as a function of pump-probe separation and time delay for $E = 0, 33, 67, 100\,\mathrm{V\,cm}^{-1}$, respectively. The dotted lines are determined by the drift velocity of the spin packet. drifts in the electric field, as expected, but it also coherently precesses in time about an internal magnetic field B_{int} generated by SO coupling for momentum $k \neq 0$. The precession angle is in excess of 3π over 60 μm in 13 ns and is proportional to the electric field. To accurately characterize B_{int}, KR is measured as a function of an *external* magnetic field B_{ext}. As in the case of time-resolved KR, the spin polarization signal oscillates and decays in time according to $\theta_0 \exp(-\Delta t/T_2^*)\cos(g\mu_{\mathrm{B}}B\Delta t/\hbar)$, where Δt is the pump-probe time delay (in these measurements, fixed at 13.1 ns), θ_0 is the initial amplitude at $\Delta t = 0$, T_2^* is the transverse spin coherence time, g is the electron g-factor, and B is the magnitude of the transverse magnetic field experienced by the electron spins. In the absence of an applied electric field (Figure 6, top trace), the average $k = 0$ and therefore $B_{\mathrm{int}} = 0$ and the oscillations are centered at $B = B_{\mathrm{ext}} = 0$. With an applied E perpendicular to B_{ext} (center trace), both the external and internal magnetic fields are along y and add directly so that $B = B_{\mathrm{ext}} + B_{\mathrm{int}}$ and the oscillatory signal is centered at $-B_{\mathrm{int}}$. For E parallel to B_{ext}, B_{int} is perpendicular to B_{ext} (Kato, Myers, Gossard and Awschalom, 2004a; Sih *et al*., 2006a) resulting in a total field magnitude of $B = \sqrt{B_{\mathrm{ext}}^2 + B_{\mathrm{int}}^2}$ which is always greater than zero for a nonzero B_{int}, causing suppression of the center peak (bottom trace).

In both cases in the preceding text, with nonzero electric field the amplitude of the signal decreases with increasing voltage, which is further investigated by spatially separating the pump and the probe by a distance d along the direction of E (Figure 7). Owing to the laser profile of the pump beam, the optically injected spins have a Gaussian spatial

Figure 6. profile which is centered at $d = 0$ when $E = 0$. An applied voltage ($E \neq 0$) imparts a nonzero average momentum k to the injected spin packet, causing it to drift with an average velocity $v_{\rm d}$. Spins at the leading edge of the packet experience a larger $B_{\rm int}$ than the trailing edge. This variation is due to the spread in the drift velocities of the spin packet arising from spin diffusion. The reported value of $B_{\rm int}$ for each E are obtained from a linear fit at the center of the spin packet, and is observed to be more than 20 mT. The spin splitting arising from this $B_{\rm int}$, $\Delta_0 = g\mu_{\rm B}B_{\rm int}$, is plotted as a function of $v_{\rm d}$. Figure 7 (inset) shows a phenomenological linear relation $\Delta_0 = \beta v_{\rm d}$. In the data presented, $\beta = 99$ neV ns μm^{-1}, while in an unstrained sample (without substrate removal) β is almost an order of magnitude smaller, decisively linking the internal magnetic field to the strain-induced spin splitting in the semiconductor.

The electrical manipulation of spin states discussed so far still requires the creation of coherent spins by optical injection. Encoding of spin information without optical or magnetic techniques offers a significant step toward an all-electrical protocol for spintronic devices. Early theoretical work points out the possibility of using a current flow to obtain magnetization in materials lacking inversion symmetry (Levitov, Nazarov and Eliashberg, 1985) (such as the zinc-blende semiconductors n-GaAs and n-ZnSe). Prior experiments for detection of current-induced spin polarization (CISP) in other systems (Hammar, Bennet, Yang and Johnson, 1999; Vorob'ev *et al*., 1979) had added complications.

The same materials and techniques described above can be used to investigate CISP. Figure 8(a) shows the measurement geometry for studying CISP in an n-$In_{0.07}Ga_{0.93}As$ channel with a built-in strain field. An alternating electric field with amplitude $E = V_{\rm pp}/(2l)$ is established along the InGaAs channel of width w and length l. The current-induced KR is lock-in detected and is measured as a function of magnetic field $B_{\rm ext}$ applied parallel to the alternating E (Figure 8b). The curves in Figure 8(b) can be explained by assuming a constant orientation rate γ for spins polarized along the y axis. In a similar process to the Hanle measurement (Figure 2a), the z component of spin per unit volume $\rho_{\rm z}$ can be written as

$$\rho_{\rm z} = \int_0^\infty {\rm d}t\gamma \exp(-t/T_2^*)\sin(\omega_{\rm L}t) = \rho_{el}\frac{\omega_{\rm L}T_2^*}{(\omega_{\rm L}T_2^*)^2 + 1} \quad (3)$$

where γ is the number of spins oriented along the y axis per unit time per unit volume, T_2^* is the transverse spin coherence time, $\omega_{\rm L} = g\mu_{\rm B}B/\hbar$ is the electron Larmor frequency, and $\rho_{\rm el} = \gamma T_2^*$ is the steady-state spin density due to electrical excitation. The upper limit for the integration is taken as infinity because the modulation period is much longer than T_2^* . This odd Lorentzian shape is indicative of spins generated in plane and perpendicular to E. Temperature dependence of this effect shows $\rho_{\rm el}(\sim 10\,\mu{\rm m}^{-3})$ not varying significantly up to $T = 60$ K. At higher T, $\rho_{\rm el}$ becomes smaller due to the decline of T_2^* , and is below the noise level for $T > 150$ K. Similar measurements in 1.5 μm-thick n-ZnSe samples yield a $\rho_{\rm el} \sim 12\,\mu{\rm m}^{-3}$ at $T = 20$ K, with CISP signal persisting up to room temperature.

Although qualitatively understood as arising from SO coupling, the microscopic origin of CISP is not well understood. Strain-enhanced inversion asymmetry terms in the Hamiltonian manifest as $B_{\rm int}$ and could generate the

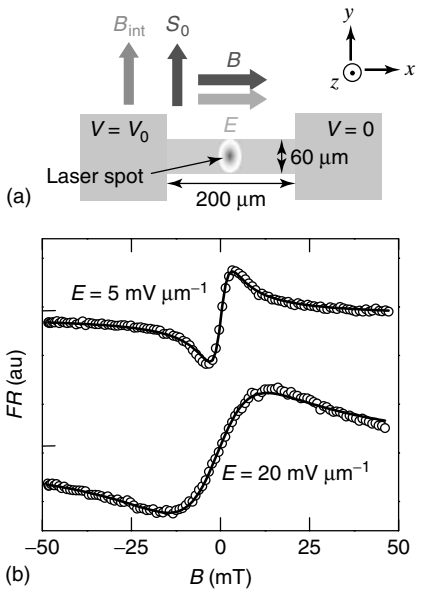

Figure 8. (a) Schematic of the device and geometry in measuring current-induced spin polarization. Squares are the metal contacts at the ends of the channel. (b) Voltage-induced FR as a function of B_{ext} for $E = 5$ and $20\,\text{mV}\,\mu\text{m}^{-1}$ with $\mathbf{E}||[1\bar{1}0]$. spin polarization. In general, the internal magnetic field strength shows a close correlation to the amount of strain in *n*-GaAs structures, but the CISP shows little correlation to the strength of B_{int}. In the experiment with *n*-ZnSe epilayers, the CISP is comparable in magnitude to that observed in GaAs, which is most surprising, since no B_{int} is measured in these thick *n*-ZnSe samples.

4 EXPERIMENTAL OBSERVATION OF THE SPIN HALL EFFECT

Electrically induced spin polarization can also be generated when current flows in a semiconductor with SO coupling, where carriers can be deflected in spin-dependent directions through the spin Hall effect. The spin Hall effect refers to the generation of a spin current transverse to a charge current in the absence of an applied magnetic field. A pure spin current can be interpreted as an equal number of spin-up and spin-down electrons moving in opposite directions, resulting in a flow of a spin angular momentum with no net charge current. The source of the transverse spin current can be either extrinsic or intrinsic spin-orbit mechanisms, analogous to the origin of the anomalous Hall effect. The extrinsic spin Hall effect was first predicted due to spin-dependent scattering off impurities in a semiconductor crystal (D'yakonov and Perel, 1971b). SO coupling mixes spin and momentum eigenstates leading to skew and side-jump scattering mechanisms which drive the transverse spin current (Engel, Halperin and Rashba, 2005). More recently, an intrinsic spin Hall effect was predicted as arising from the momentum-dependent internal magnetic field B_{int} which arises from SO coupling (Murakami, Nagaosa and Zhang, 2003; Sinova *et al*., 2004). These Dresselhaus and Bychkov–Rashba fields arise from bulk inversion asymmetry or structural inversion asymmetry, respectively, and generate spin splitting in the electron bands for momentum $k \neq 0$ in semiconductors without an inversion center. These effective internal magnetic fields are inherent in the band structure of the crystal and do not depend on the presence of impurities.

4.1 Observation of the spin Hall effect in bulk Gallium arsenide

The first optical detection of the spin Hall effect (Kato, Myers, Gossard and Awschalom, 2004c) was performed on a series of 2 μm-thick GaAs epilayers with a Si doping density $n = 3 \times 10^{16}\,\text{cm}^{-3}$ grown by MBE on a (001) semi-insulating GaAs substrate. The epilayers were patterned by photolithography and etched into a semiconducting channel with a metallic contact on each end. The structures are cooled to $T = 30\,\text{K}$ in a helium flow cryostat. When current is sent through the semiconducting channel, a transverse spin current develops due to the spin Hall effect. This pure spin current cannot be measured directly, but it does result in a spin accumulation on the edges of the channel, which can be detected optically.

Figure 9(a) shows an unstrained GaAs sample with a channel of width $w = 77\,\mu\text{m}$ and length $l = 300\,\mu\text{m}$ patterned parallel to the [110] crystallographic direction. The sample is measured with a scanning Kerr microscope (Stephens *et al*., 2003) which provides ∼1 μm spatial resolution to detect the KR of a linearly polarized 825-nm-wavelength probe beam. Figure 9(b) shows KR as a function of external applied magnetic field B_{ext}. The curves are analogous to the Hanle effect (Meier and Zakharechenya, 1984) previously discussed in terms of both luminescence polarization and DC Kerr measurements. Spin polarization is generated out of the plane of the channel by the spin Hall effect, which precesses about the transverse magnetic field B_{ext} as it decoheres. The KR of the spatially resolved probe measures the time-averaged polarization projected along the beam direction (z axis), which is well-fit by a Lorentzian function given by

$$\theta_{\text{K}} = \frac{\theta_0}{(\omega_{\text{L}}\tau)^2 + 1} \tag{4}$$

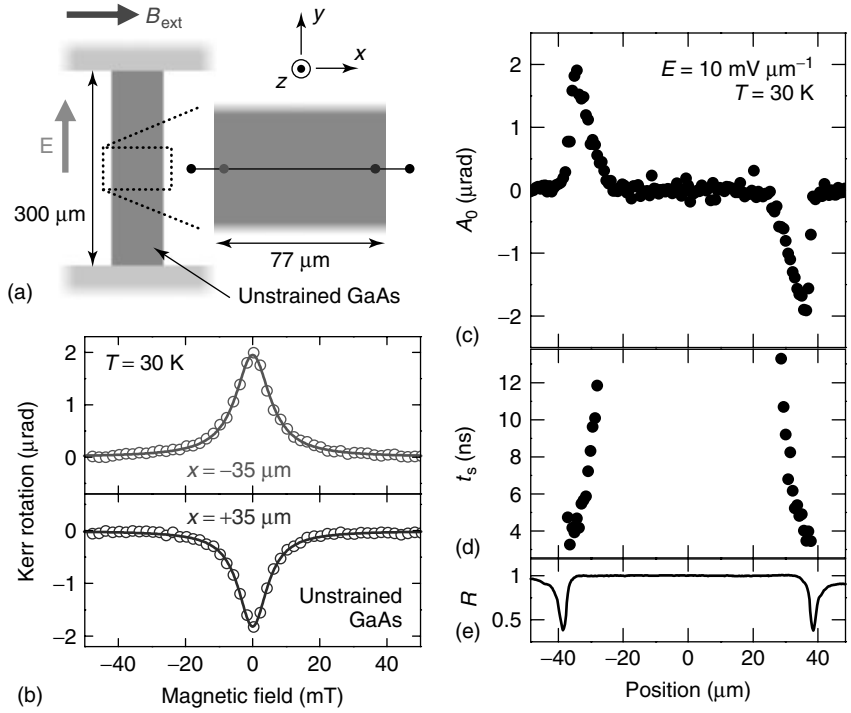

Figure 9. The spin Hall effect in unstrained GaAs. Data are taken at $T = 30\,\mathrm{K}$ and a linear background has been subtracted from each B_{ext} scan. (a) Schematic of the unstrained GaAs sample and the experimental geometry. (b) Typical measurement of KR as a function of B_{ext} for $x = -35\,\mu\mathrm{m}$ (top) and $x = +35\,\mu\mathrm{m}$ (bottom) for $E = 10\,\mathrm{mV}\,\mu\mathrm{m}^{-1}$. Solid lines are fits as explained in text. (c)–(d) Spatial dependence of peak KR A_0 and spin lifetime across the channel, respectively, obtained along the linecut in (a). (e) Reflectivity R as a function of x. R is normalized to the value on the GaAs channel. The two dips indicate the position of the edges and the width of the dips gives an approximate spatial resolution. (Reprinted with permission Kato *et al.*, copyright 2004, AAAS.)

where θ_0 is the amplitude of KR and $\omega_{\mathrm{L}} = g\,\mu_{\mathrm{B}} B/\hbar$. ($g = -0.44$ for this sample as measured using time-resolved KR). This Lorentzian form is analogous to equation 3, except the spin polarization is generated out of plane along the probe beam direction rather than in the plane. θ_0 is of equal magnitude and opposite sign for the two edges of the sample (Figure 9c), as expected for the spin Hall effect (Hirsch, 1999; Zhang, 2000). The density of accumulated spin polarization (which is proportional to θ_0) is a maximum at the edges of the channel and decreases with distance from the edge. The accumulation can be quantitatively analyzed using solutions to a drift-diffusion model for the spin current (Zhang, 2000), giving a spin diffusion length of $L_{\mathrm{s}} \sim 3 - 4\,\mu\mathrm{m}$.

A two-dimensional spatially resolved image of the entire channel shows the electrically induced spin accumulation of opposite sign on either edge of the sample (Figure 10). The polarization is uniform over the length of the channel but decreases near the contacts as would be expected from the unpolarized electrons injected at the contacts.

The origin of the spin Hall effect in the GaAs epilayers is likely extrinsic spin-dependent scattering. The k-dependent spin splitting in unstrained GaAs is weak, and similar observations in strained InGaAs show no marked crystallographic direction dependence that would link the spin accumulation to the band structure. Measurements in strained InGaAs channels show similar spin accumulation with an additional B_{int}, but the presence of this intrinsic SO field does not qualitatively change the effect.

4.1.1 The intrinsic spin Hall effect in a two-dimensional hole gas

The spin Hall effect was also observed in a two-dimensional hole gas (Wunderlich, Kaestner, Sinova and Jungwirth, 2005). In this experiment, a novel p−n junction light-emitting diode microdevice in coplanar geometry was fabricated using optical and electron beam lithography in modulation-doped AlGaAs/GaAs heterostructures grown by MBE (see Figure 1 in Wunderlich, Kaestner, Sinova and Jungwirth, 2005). The sample was cooled to a temperature of 4.2 K, and an in-plane electric field is applied along the p channel of the microdevice (see Figure 3 in Wunderlich, Kaestner, Sinova and Jungwirth, 2005) generating a nonzero out-of-plane hole spin polarization. The polarization of the emitted light depends on the direction of the hole spins,

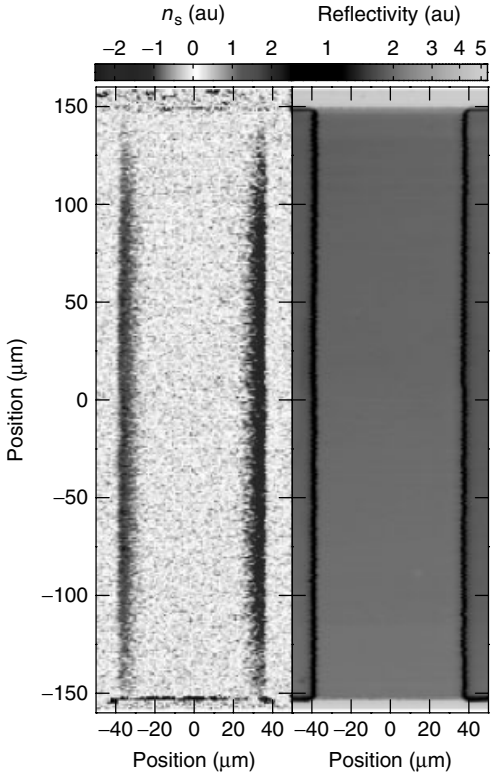

Figure 10. Two-dimensional images of spin density n_s (left) and reflectivity R (right) for an unstrained GaAs channel measured at $T = 30\,\mathrm{K}$ and $E = 10\,\mathrm{mV\,\mu m^{-1}}$. The region on the left (right) corresponds to the spin polarization in the $z(-z)$ direction. (Reprinted with permission Kato *et al*., copyright 2004, AAAS.)

allowing optical detection of the spin polarization at the edges of the p channel. The polarization of this light changes sign for the opposite edges of the channel. In addition, the polarization of the emitted light also changes sign when the direction of the applied electric field is reversed, consistent with the predicted spin Hall effect. In contrast to the measurement of extrinsic spin Hall effect through KR, microscopic quantum transport calculations suggest that the observed spin Hall effect is intrinsic owing to the strong SO coupling of the two-dimensional hole gas (Wunderlich, Kaestner, Sinova and Jungwirth, 2005).

4.1.2 The spin Hall effect in a two-dimensional electron gas

The spin Hall effect can also be measured in two-dimensional electron systems, first done in modulation-doped single quantum wells are grown by MBE on (110) semi-insulating GaAs substrates (Sih *et al*., 2005). Similar devices and measurement techniques are used as those used in the original KR measurement of the spin Hall effect. Figure 11(c) shows a one-dimensional spatial profile of the spin accumulation

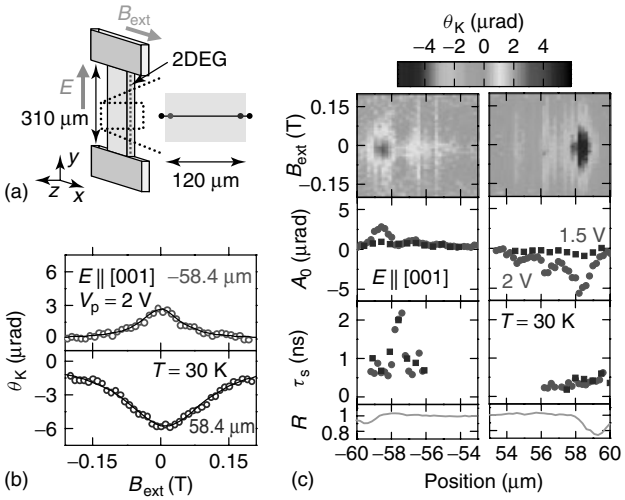

Figure 11. Spin Hall effect in a two-dimensional electron gas (a) Device schematic and measurement geometry. (b) Kerr rotation (hollow symbols) and fits (lines) as a function of applied in-plane magnetic field B_{ext} for $x = -58.4\,\mu\mathrm{m}$ (top) and $x = +58.4\,\mu\mathrm{m}$ (bottom). The channel has width $w = 120\,\mu\mathrm{m}$, length $l = 310\,\mu\mathrm{m}$, and mesa height $0.1\,\mu\mathrm{m}$. A linear background is subtracted for clarity. (c) B_{ext} scans as a function of position near the edges of the channel of a device for $V_p = 2\,\mathrm{V}$. Amplitude A_0, spin coherence time τ_s, and reflectivity R are plotted for $V_p = 1.5\,\mathrm{V}$ (squares) and $2\,\mathrm{V}$ (circles). (See the original figure in color in Sih *et al*., 2005.) (Reprinted with permission V. Sih *et al*., copyright 2005, Nature Publishing Group.)

near the edges of the channel. Two spin Hall peaks at each edge of the channel are visible, one at $x = \pm 58.6\,\mu\mathrm{m}$ and one of smaller amplitude at $x = \pm 56.4\,\mu\mathrm{m}$. This structure could be due to an additional contribution from spin-polarized carriers undergoing spin precession about the in-plane Bychkov–Rashba field as they diffuse from the edges toward the center of the channel.

Optical measurements in (110)-oriented quantum wells also allow study of the two spin-orbit mechanisms responsible for internal magnetic fields by allowing one to isolate the contributions of the Dresselhaus and Bychkov–Rashba effects. In two-dimensional systems, the Dresselhaus field is oriented along the growth direction in (110) quantum wells, whereas this field is in plane in (001) quantum wells. Since the Dresselhaus and Bychkov–Rashba fields are mutually perpendicular, one can observe a dependence of the CISP on the direction of the current flow in the semiconductor and the interplay of the Dresselhaus and Bychkov–Rashba fields (Sih *et al*., 2005).

4.1.3 Evidence of pure spin current generated by the spin Hall effect

Despite the strong evidence for the observation of the spin Hall effect, the source of the spin accumulation is not

clear. Theory of the spin Hall effect would suggest that a transverse spin current is created in the bulk of the semiconductor channel, but since spin is not a conserved quantity in a material with SO interactions, the very concept of a spin current is not well defined (Sih *et al.*, 2005). This difficulty causes uncertainty about the existence of a real pure spin current causing spin accumulation in the experiments. Indeed, models of spin accumulation are sensitive to the boundary conditions imposed at the edges (Tse, Fabian, Zutic and Das Sarma, 2005). Edge effects such as carrier depletion can cause local effective magnetic fields, which could potentially give rise to spin accumulation without the production of a bulk spin current.

Devices can be engineered to distance the boundary of the current in the channel from the edges of the sample, thereby separating spin accumulation from the physical edge of the sample (Sih *et al.*, 2006b). Using the same GaAs material described previously, 60-μm-wide channels are fabricated along the $[1\bar{1}0]$ crystallographic direction with smaller 40-μm-wide channels extending from the main channel transverse to the current flow, shown schematically in Figure 12(a).

The spin polarization amplitude for a 60-μm-wide channel and for 10-, 20-, and 40-μm-wide side arms are displayed in Figure 12(b). The spin polarization amplitude near the left edge at $x = -30\,\mu\text{m}$ is unaltered in the presence of the side arms. In contrast, the spin polarization amplitude near the right edge $x = 30\,\mu\text{m}$ is modified by the addition of the side arms. The spin polarization amplitude is not always largest near the edge of the channel, indicating that the spin accumulation is not a local effect caused by the sample's physical boundary. The amplitude of the spin polarization is smaller for longer side arms at any position x, consistent with spins drifting from the main channel toward the end of the side arms. The measurements can be successfully modeled by a spin drift-diffusion model (Crooker *et al.*, 2005; Lou *et al.*, 2006) of a spin current being generated throughout the bulk of the channel and drifting into the side arms, where there is no generation of spin polarization since there is negligible electron current (Figure 12). These measurements demonstrate that the spin polarization from the spin Hall effect is not restricted to the sample edges. The spin current generated in the bulk of the channel can drive spin transport over length scales significantly longer than the spin diffusion length $L_s = 9\,\mu\text{m}$ in the sample.

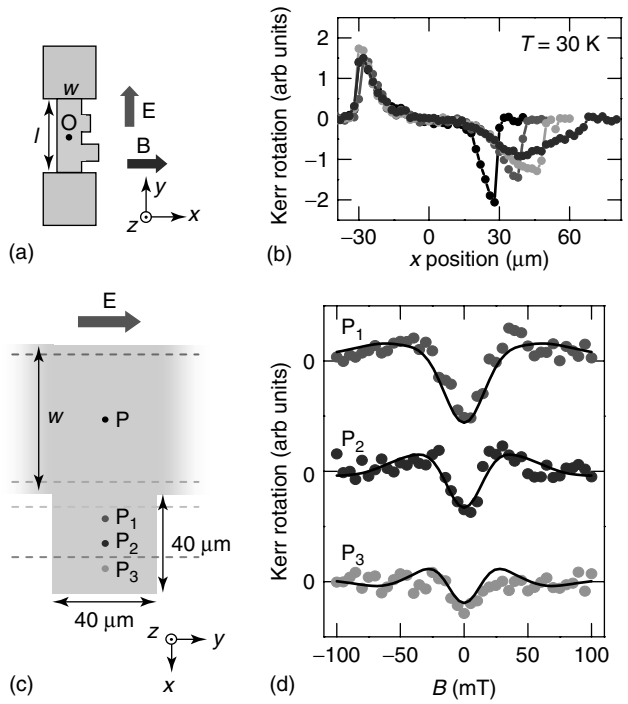

Figure 12. (a) Measurement schematic and experimental geometry. The center of the channel is taken to be the origin O. (b) Spin polarization amplitude as a function of position measured for the channel and with 10 μm, 20 μm, and 40 μm side arms. Data are taken at $T = 30\,\text{K}$ and $V = 6\,\text{V}$. (c) Measurement schematic showing where the spatial scans are made. P indicates the position $(x, y) = (0\,\mu\text{m}, -50\,\mu\text{m})$. (d) Kerr rotation as a function of magnetic field for three different x positions at $y = -50\,\mu\text{m}$ on the 40 μm side arm. Measurements are shown for $x = 40\,\mu\text{m}$ (P_1, top), $x = 50\,\mu\text{m}$ (P_2, middle) and $x = 60\,\mu\text{m}$ (P_3, bottom). Solid lines are calculated from a model that accounts for spin drift. (Reprinted with permission Sih *et al.*, copyright 2006, American Physical Society.)

4.2 Electrical measurement of the spin Hall effect

Optical measurements enable measurement of the spin Hall effect through the direct connection between light polarization and carrier spin through the selection rules in zinc-blende semiconductors. Since the spin Hall effect is an example of all-electrical generation of spin, it is desirable to be able to detect spin accumulation entirely on-chip without the need for external laser systems. Further, electrical detection may enable a more direct measurement of the spin Hall conductivity of a material. Various proposals have been made to measure the spin Hall effect electrically in metals and semiconductors (Hankeiwicz, Molenkamp, Jungwirth and Sinova, 2004; Shchelushkin and Brataas, 2005).

Direct electronic detection of the spin Hall effect was first demonstrated in a diffusive metallic conductor (aluminum) (Valenzuela and Tikham, 2006). In this measurement, the device, which consists of an aluminum strip with side arms and a ferromagnetic electrode, was fabricated using electron beam lithography and a shadow mask evaporation technique (see Figure 1 in Valenzuela and Tikham, 2006). The measurements are performed at 4.2 K. Spin-polarized electrons are injected from the ferromagnetic electrode into

the Al strip by applying a voltage between the electrode and one end of the Al strip. The spin-polarized charge current flowing in the Al strip creates a spin current flowing in the opposite direction due to diffusion of spin-polarized carriers. SO interactions separate the spin-up and spin-down electrons generating a transverse spin current that leads to spin accumulation at the edges of the Al strip. Unequal numbers of spin-up and spin-down electrons in the Al strip leads to a charge imbalance across the strip producing a spin Hall voltage proportional to the spin polarization. This process is based on the same principles as the anomalous Hall effect, but occurs in a nonmagnetic material. The measured spin conductivity is consistent with the result of the theoretical calculations using semiclassical Boltzmann approximation (Zhang, 2000). The measured spin Hall voltage in this experiment is of the order of 10 nV, and the corresponding spin Hall conductivity (σ_{SH}) is approximately $10^{-3}\Omega^{-1}\,m^{-1}$ which is 10^{-4} times smaller than the charge conductivity (σ_C) in Al.

4.3 The spin Hall effect at room temperature in Zinc selenide

Optical measurements of the spin Hall effect and other forms of all-electrical spin generation were typically performed in the III–V semiconductor GaAs, which has long spin coherence times as well as strong SO coupling effects. Despite the typically weaker SO coupling in II–VI semiconductors (Winkler, 2003), both CISP and the spin Hall effect have been observed through KR in 1.5-μm-thick *n*-type Cl-doped ZnSe epilayers with $n = 9 \times 10^{18}\,cm^{-3}$ (Stern *et al*., 2006). Observation of the spin Hall effect is highly dependent on *n*-doping, as no spin Hall signature is measured in samples with lower *n*.

In this experiment, careful attention was paid to measure the sign of the spin accumulation, with the results shown in Figure 13(a). The spin Hall conductivity is measured to be of the same order of magnitude and the same sign to what has been predicted by theory for GaAs with a dominant extrinsic spin Hall effect (Engel, Halperin and Rashba, 2005; Tse and Das Sarma, 2006). ZnSe exhibits long spin coherence times even up to room temperature (Malajovich *et al*., 2000), and both the CISP and the spin Hall effect persist up to room temperature as well (Figure 13d and e) with little decrease in the spin diffusion length and only an order of magnitude decrease in spin polarization and spin Hall conductivity. The spin Hall conductivity is proportional to the charge conductivity, suggesting extrinsic spin-orbit mechanisms. This result is the first evidence of all-electrical generation and separation of spin polarization

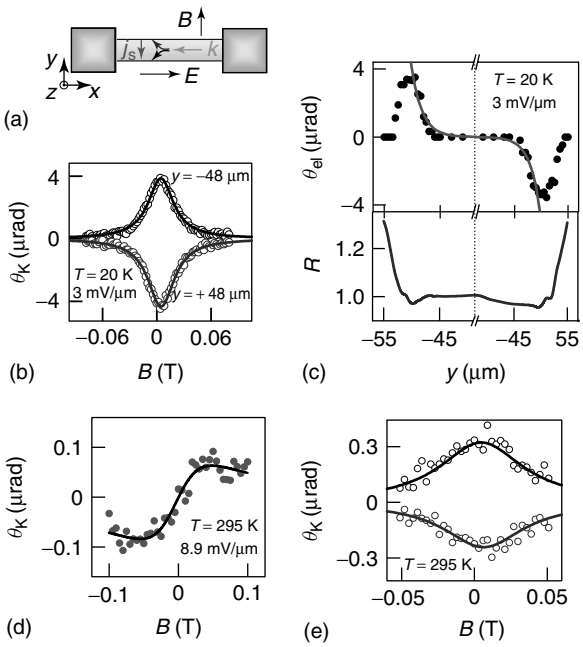

Figure 13. (a) Schematic showing the measurement geometry for the spin Hall effect, with $B_{ext}||x$. For $E > 0$, $j_x^s < 0$. (b) θ_K (open circles) and fits (lines) at $y = 0\,\mu m$ as a function of B_{ext} for $x = -48\,\mu m$ (top) and $x = +48\,\mu m$ (bottom) at $T = 20\,K$. (c) Spatial dependence of the fit parameters θ_{el} and τ_s, as well as the reflectivity R of the beam (normalized to 1 at $x = 0$). (d) KR (circles) and fit (line) of CISP at room temperature. Adjacent-point averaging was done to improve signal-to-noise. (e) KR (circles) and fits (lines) of spin Hall polarization at $x = -48\,\mu m$ (top) and $x = +48\,\mu m$ (bottom) for $T = 295\,K$. at room temperature, hinting at the possibility of utilizing these phenomena in functional spintronics devices.

5 SPIN COHERENCE IN MAGNETIC SEMICONDUCTORS

In previous sections, we discussed the possibilities for generating and manipulating coherent ensembles of spins in semiconductors using optical and electrical techniques. Spins also interact with local moments in a semiconductor, such as magnetic impurities. The interactions between coherent spins and magnetic moments in a semiconductor offer a pathway for realizing hybrid materials which can take advantage of the long-lived spins of localized impurities and the ability to optically and electrically manipulate coherence in semiconductors.

Magnetic coupling between two spins in most semiconductors is dominated by the electrostatic exchange interaction. In semiconductors doped with only small amounts of magnetic atoms, even the exchange interactions are too

short-ranged for magnetic ordering to occur. But, the itinerant band carriers are strongly affected by exchange with the doped magnetic atoms in the lattice due to their spatial overlap with the random local magnetic moments. Even in dilute magnetic systems, exchange interactions are not negligible, causing a giant Zeeman spin splitting in a magnetic field where the energy difference between spin-up and spin-down states of electrons can be increased by orders of magnitude.

Carrier–ion spin interactions in dilute magnetic semiconductors include both direct and kinetic exchange processes (Kacman, 2001). The interaction between the s-symmetry conduction band or p-symmetry valence band and the localized d states of magnetic impurities are known and the s–d and p–d exchange interactions, respectively. In this section, we will discuss a series of phenomena that arise in magnetic semiconductors due to the sp–d exchange interactions between spin-polarized carriers and a dilute system of magnetic moments doped into the host semiconductor.

5.1 Manipulating carrier exchange interactions in semiconductors

Early experiments on spins in magnetic semiconductors were typically performed in II–VI semiconductors where high solubility of magnetic dopants is achieved because of the compatible valence between typical transition-metal dopants and the group II cations. Conduction and valence band spins can be accessed through optical techniques such as photoluminescence and absorption, where spin energy splittings can be readily extracted. Treating sp–d exchange as a mean-field, dilute paramagnetic impurities induce an additional effective magnetic field on the carriers. Time-resolved measurements of coherent spin precession in paramagnetic semiconductors reveal an enhanced spin-flip scattering due to the magnetic impurities and an enhanced spin-splitting energy. The Larmor precession ν_{L} in a transverse magnetic field (e.g., along the x axis) is proportional to the total conduction band spin-splitting energy between spin-up and spin-down electrons ($\Delta E = E_{\uparrow} - E_{\downarrow}$) and can be expressed in terms of the Zeeman splitting (ΔE_{g}), and the s–d exchange splitting (ΔE_{sd}):

$$h\nu_{\mathrm{L}} = \Delta E = \Delta E_g + \Delta E_{\mathrm{sd}} = g\mu_{\mathrm{B}} B_x - xN_0\alpha \langle S_x \rangle \quad (5)$$

Here $\langle S_x \rangle$ is the component of Mn^{2+} spin along B, x is the concentration of magnetic ions, and $N_0\alpha$ is the s–d exchange parameter. Measuring the precession frequency of electron spins in a paramagnetic semiconductor allows extraction the s–d exchange energy in the material (Figure 14).

The strength of sp–d exchange interactions depends directly on the overlap of the carrier wave functions and the d orbitals of magnetic atoms. A graded parabolic

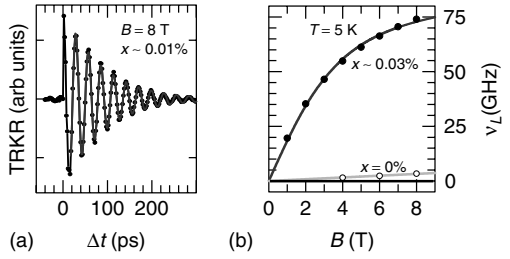

Figure 14. (a) Coherent electron spin precession in a paramagnetic AlGaAs/$Ga_{1-x}Mn_xAs$ quantum well. (b) Enhancement of the Larmor precession frequency in a similar quantum well (solid data) compared with the linear frequency of a nonmagnetic quantum well. The Brillouin function shape from the magnetization of the paramagnetic Mn impurities is evident in the curvature of ν_{L} with magnetic field. (Reprinted with permission Myers *et al*., copyright 2005, American Physical Society.)

quantum well allows for direct tuning of the exchange energy of electrons by electrical gating after the heterostructure growth. In an experiment by Myers *et al*. (2005a), a gated quantum well of $Zn_{1-x}Cd_xSe$ with x parabolically graded from $x = 0$ in the barriers to $x = 0.15$ at the center is grown by MBE. Four submonolayer digital regions of MnSe are deposited in the center of the well. When an electrical bias is applied to a parabolic potential, the center position of the confined electron will shift with minimal distortion in the wave function (Figure 15a). The tails of the electron wave function will overlap with the MnSe layers less than the center, thereby allowing direct electrical tuning of the s–d exchange in the device. Time-resolved Kerr rotation (TRKR) is used to measure the precession frequency of the electrons as a function of the electrical bias (Figure 15b). Whereas spins in a nonmagnetic quantum well show little tuning, the precession frequency of the electrons in the magnetic quantum well have an effective enhancement to their g-factor from the magnetic layers which tunes as the bias is changed. The TRKR measurements also reveal that the Mn spin system is tipped by the p–d exchange away from its equilibrium magnetization in a process that will be discussed in more detail later. The precession frequency of the photoexcited carriers can be further tuned by laser excitation energy. The s–d exchange is effectively reduced using higher laser energy, At higher excitation energies, the carriers are injected in higher exciton sublevels of the quantum well whose wave functions do not overlap as efficiently with the Mn^{2+}-doped layers as the s-symmetry ground state. The resulting effective electron g-factor is reduced closer to the nonmagnetic value (Figure 15c).

The sp–d exchange interactions are sensitive to changes in band symmetry caused by quantum confinement. Figure 16 shows measurements of the s–d exchange energy extracted from TRKR of coherent spin precession in $Ga_{1-x}Mn_xAs$ quantum wells of varying confinement energy (Myers *et al*.,

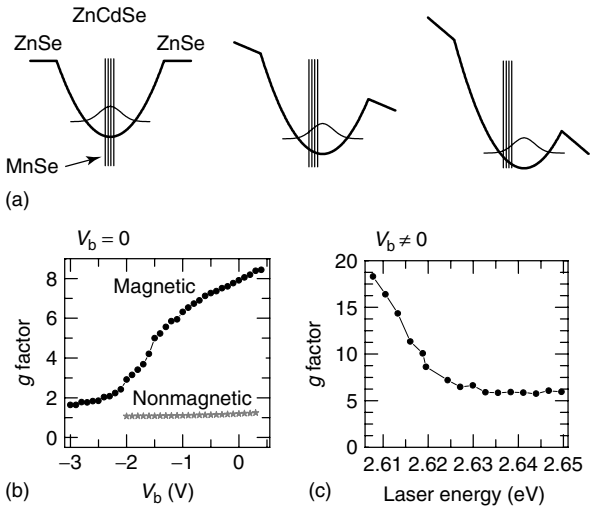

Figure 15. (a) Schematic of a parabolic ZnSe/ZnCdSe quantum well with digital MnSe doping in the center. Under electrical bias ($V_b \neq 0$), the parabolic potential is translated, which translates the electron wave function with minimal distortion and alters the effective overlap of the electron wave function with the magnetic region. (b) Tuning of the electron effective g-factor (proportional to ΔE) with bias V_b showing the increased exchange coupling near zero-bias. (c) Tuning of the effective g-factor with the laser energy showing the decreased s-d interaction for electrons in higher sublevels. (Reprinted with permission Myers *et al*., copyright 2005, American Physical Society.)

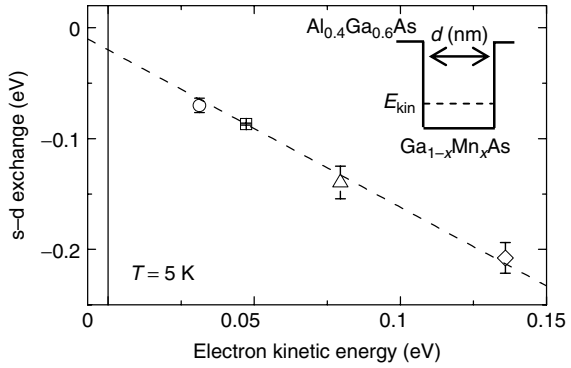

Figure 16. Variation of the s−d exchange in AlGaAs/GaMnAs quantum wells with the kinetic energy of the ground state (inset). The antiferromagnetic s−d exchange was originally presented in Myers *et al*. (2005b). (Reprinted with permission Myers *et al*., copyright 2005, American Physical Society.)

2005b; Poggio *et al*., 2005). The quantum well confinement is controlled varying the quantum well width. The s−d exchange becomes more antiferromagnetic with increasing confinement energy. This trend was first observed in CdMnTe quantum wells (Mackh, Ossau, Waag and Landwehr, 1996) and explained as a confinement-induced band mixing (Merkulov *et al*., 1999). Quantum confinement increases the kinetic energy of electrons in the quantum wells, bringing the electrons away from the zone center in k space. Away from $k = 0$, mixing of the conduction and valence bands alters the symmetry of electron states. Since p−d exchange is antiferromagnetic (negative), the partial p symmetry of the conduction band for $k \neq 0$ causes the s−d exchange to become more antiferromagnetic. This phenomenon is general to both II−VI and III−V paramagnetic quantum wells, providing a broad method of engineering electron exchange interactions in heterostructure devices.

5.2 Coherent spins and local magnetic moments

In addition to the effects of magnetic interactions on carrier spins discussed in the preceding text, spin polarization in the bands also influences the magnetic atoms in the semiconductor, in some cases inducing magnetic order. One of the earliest indications of the importance of carrier spin to the magnetic ordering of a magnetic semiconductor was the bound magnetic polaron, invoked to explain a decrease of resistivity with increasing magnetic field in Eu-chalcogenides (von Molnar and Methfessel, 1967; Kasuya and Yanase, 1968). A bound magnetic polaron forms when carriers are captured near magnetic donors or acceptors. Exchange interactions between the trapped spins and the paramagnetic impurities align nearby magnetic spins, causing an indirect, band-mediated ferromagnetism between the magnetic impurities. The resulting 'ball' of polarized atoms around the trapped carrier is the magnetic polaron. This dynamic magnetic ordering into polarons has been found to be a universal phenomenon in magnetic semiconductors (Kasuya and Yanase, 1968).

The dynamics of polaronic spin ordering can be observed optically with TRKR, as was first done in CdMnTe (Awschalom *et al*., 1985). In this experiment, a strong laser pump pulse injects spin-polarized acceptor bound excitons into the material. A subsequent probe pulse does not measure the bound excitons, but rather detects a low-temperature magnetization signal which increases rapidly over ∼200 ps before decaying away. Exchange interactions between the photoexcited electron and the Mn ions surrounding the exciton polarize the spins of the magnetic impurities forming the polaron. Larger magnetic fields increase the strength of the resulting Mn polarization detected. The magnetization disappears above $T = 10$ K, but at low temperatures the time-resolved technique captures this dynamical magnetization of the semiconductor in real time.

Angular momentum from photo-injected spin-polarized carriers can be coherently transferred to the magnetic system. TRKR measurements from magnetic ZnSe/(Zn, Cd, Mn)Se quantum wells reveal THz-frequency electron spin precession at the enhanced g-factor due to s−d exchange

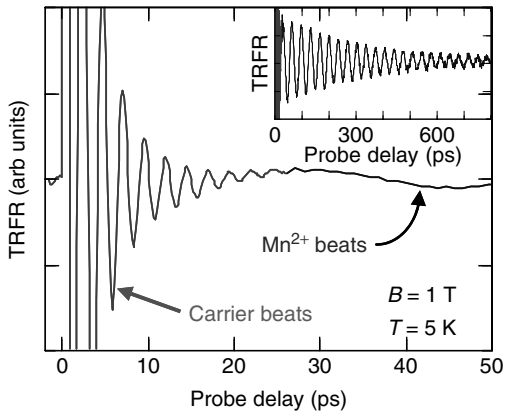

Figure 17. TRFR from a ZnSe/(Zn, Cd, Mn)Se quantum well showing the s−d exchange-enhanced THz spin precession of the electrons transitioning into the slower GHz spin precession of the Mn^{2+} moments. The inset shows the Mn spin beats persisting for ∼1 ns, much longer than the photoexcited carrier beats. (Reprinted with permission Crooker *et al*., copyright 1996, American Physical Society.)

(Figure 17). Further, the decoherence time of the electrons is only ∼20 ps due to the enhanced spin-flip relaxation from the magnetic impurities (Crooker *et al*., 1996).

The measurements from these quantum wells also reveal an oscillating component, which persists for nanoseconds longer than the spin polarization of the optically injected electrons (Figure 17). The frequency of this long-lived precession corresponds to $g = 2$, and is unchanged with temperature or sample parameters. The photoexcited carriers impart a transverse magnetization to the ensemble of Mn spins, which then precess at microwave frequencies about the applied magnetic field independently of the electron spins. This transfer of angular momentum from the optically injected spin-polarized carriers occurs through the p−d exchange coupling. The hole magnetization provides an effective exchange field which tips the Mn spin polarization away from the equilibrium direction of the external field. The magnetization vector precesses around the magnetic field at $g = 2$ as detected in the TRKR as if it were optically injected by the pump beam. This result demonstrates that spin information can be coherently transferred to the magnetic lattice where it will remain long after the original spin-polarized carriers have recombined.

5.3 Ferromagnetic semiconductors and outlook

When the concentration of magnetic atoms and carriers is high enough in some magnetic semiconductors, the delocalized carriers can mediate a ferromagnetic interaction between the magnetic impurities (Kacman, 2001). This carrier-mediated ferromagnetism was first observed in the III–V dilute magnetic semiconductors InMnAs and GaMnAs (Ohno *et al*., 1992, 1996) grown through low-temperature MBE to increase the solubility of Mn in the III–V lattice. Beyond the rich scientific interest, carrier-mediated ferromagnetism is attractive from a technological standpoint because the magnetic interaction can be electrically tuned through the electrical properties of the semiconductor (Ohno *et al*., 2000). Ferromagnetic semiconductors provide a medium to combine the capabilities of magnetic and semiconductor devices in a single material, driving research in the fields of spintronics and materials science to improve the understanding and engineering of these materials.

Because of the low-temperature MBE necessary to increase the solubility of magnetic dopants to ferromagnetic levels, the defect levels in ferromagnetic semiconductors are high. As such, optically injected spin coherence has not yet been measured in ferromagnetic III–V semiconductors. Coherent spin dynamics have recently been observed in GaMnAs quantum wells (Myers *et al*., 2005b), but the materials are only paramagnetic because of the low Mn^{2+} concentration required to observe coherent dynamics. It would be revolutionary to combine ferromagnetic semiconducting materials with the ability to manipulate coherent spin phenomena. Such a union would not only allow the scientific study of dynamic magnetization by coherent spin-polarized carriers, but also bring powerful new functionality to spintronic devices relevant for both logic and memory applications.

Quantum Computing with Spins in Solids

William A. Coish and Daniel Loss
University of Basel, Basel, Switzerland

1 INTRODUCTION

Recent advances in semiconductor spintronics and, more specifically, spin-based quantum computing in solid-state systems, have encouraged significant research efforts in the last years (Prinz, 1998; Wolf *et al*., 2001; Awschalom, Loss and Samarth, 2002). Much of this research is motivated by pressure on the electronics industry to maintain Moore's-law growth in systems with components that are very quickly approaching the nanoscale, where quantum mechanics becomes important (ITRS, 2005). Additionally, nanoscale devices provide a unique opportunity to study the fundamental physics of quantum phenomena in a controllable environment.

Independent of the particular motivation, if quantum information processing is to progress beyond basic proof-of-principle experiments, it must be based on a viable, scalable qubit (a quantum-mechanical two-level system, which can be placed in an arbitrary superposition of its basis states: $|\psi\rangle = a\,|0\rangle + b\,|1\rangle$). The two states of single electron spins ($|\uparrow\rangle = |0\rangle$ and $|\downarrow\rangle = |1\rangle$), confined to semiconductor quantum dots (the Loss–DiVincenzo proposal), are one such qubit (Loss and DiVincenzo, 1998). These qubits are viable, in the sense that they make use of fabrication techniques and electrical control concepts that have been developed over the last five decades in research laboratories and industry. The secret to scalability in the Loss–DiVincenzo proposal lies in local gating; this proposal would implement gating operations through the exchange interaction, which can be tuned locally with exponential precision, allowing pairs of neighboring qubits to be coupled and decoupled independently. This is to be contrasted with proposals that make use of long-ranged interactions (e.g., dipolar coupling) for which scalability may be called into question. The local, tunable nature of interqubit interactions in the Loss–DiVincenzo proposal is what makes it possible to consider first isolated one-qubit (single quantum dot), then isolated two-qubit (double quantum dot) systems. Once single and double quantum dots are understood, along with environmental coupling mechanisms, a quantum computation can proceed through a series of one- and two-qubit operations, without great concern regarding interactions between three, four, and more qubits.

There are many other proposals for qubits and associated quantum control processes. Some examples include various proposals that use superconducting devices (for reviews, see Makhlin, Schön and Shnirman, 2001; Burkard, 2004),

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

proposals for 'adiabatic quantum computing', in which quantum computations are performed through adiabatic manipulation of coupling constants in physically realizable Hamiltonians (Farhi, Goldstone, Gutmann and Sipser, 2000; Farhi *et al*., 2001; Wu, Zanardi and Lidar, 2005) (this might be used to perform fast quantum simulations of, for example, superconducting pairing models (Wu, Byrd and Lidar, 2002)), electron-spin qubits encoded in two-spin states (Levy, 2002) or many-spin chains (Meier, Levy and Loss, 2003a,b) (recent work showing that such spin chains can be built-up atom-by-atom on a surface (Hirjibehedin, Lutz and Heinrich, 2006) is a possible first step to implementing such a proposal), cavity-QED schemes (Sleator and Weinfurter, 1995; Domokos, Raimond, Brune and Haroche, 1995), trapped-ion proposals (Cirac and Zoller, 1995), and so on. Each of these proposals has advantages and disadvantages. Here we do not compare the relative merits of all proposals, but instead focus on proposals involving electron spins confined to quantum dots.

Before a quantum computation can begin, the qubits in a working quantum computer must be initialized to some state, for example, $|0\rangle$. These qubits must be sufficiently isolated from the surrounding environment to reduce decoherence, there must be some way to perform fast single- and two-qubit operations in a timescale much less than the qubit decoherence time, and it must be possible to read out the final state of the qubits after any quantum computation (DiVincenzo, 2000). In the following sections, we address these issues and others which are important for the Loss–DiVincenzo proposal. In the process, we survey some recent work on quantum computing with electron spins in quantum dots.

Owing to the rapid development of this field, there have been many recent reviews on quantum-dot quantum computing. Among these numerous reviews, there has been work that focuses on single-electron charge qubits in double dots (Fujisawa, Hayashi and Sasaki, 2006), the implementation of single-electron spin resonance (ESR), and the molecular wave functions of coupled double dots (van der Wiel *et al*., 2006), various proposals for spin-based quantum computing (Cerletti, Coish, Gywat and Loss, 2005), silicon-based proposals for quantum computing (Koiller *et al*., 2005), general quantum computing in the solid state, including both quantum dots and superconducting systems (Burkard, 2004), experiments and experimental proposals for quantum-dot-confined electrons (Engel, Kouwenhoven, Loss and Marcus, 2004), the many coupling schemes and decoherence mechanisms for quantum-dot spin qubits (Hu, 2004), and optical properties of quantum dots (Hohenester, 2004). In this review, we analyze the Loss–DiVincenzo proposal from the viewpoint that this proposal can be decomposed into first single and then double quantum dots, with a special emphasis on double-dot physics.

This review is organized as follows: in Section 2, we give a brief summary of the Loss–DiVincenzo proposal for quantum computing. In Section 3, we discuss the characterization and manipulation of spin and charge states of electrons in single quantum dots. Section 4 contains a description of double quantum dots that emphasizes the single-electron regime, which is relevant for quantum-dot quantum computing. In Section 5 we survey important decoherence mechanisms for electron spins in single and double quantum dots. In Section 6, we briefly review some proposals for the generation and detection of nonlocal entanglement of electron spins in nanostructures, and in Section 7 we conclude with a brief summary of important topics for future study.

2 SPINS IN QUANTUM DOTS: AN OVERVIEW OF THE LOSS–DIVINCENZO PROPOSAL

In the original Loss–DiVincenzo proposal, the qubits are stored in the two spin states of single confined electrons. The considerations discussed in (Loss and DiVincenzo, 1998) are generally applicable to electrons confined to any structure (e.g., atoms, molecules, defects, etc.), although the original proposal focused on applications in gated semiconductor

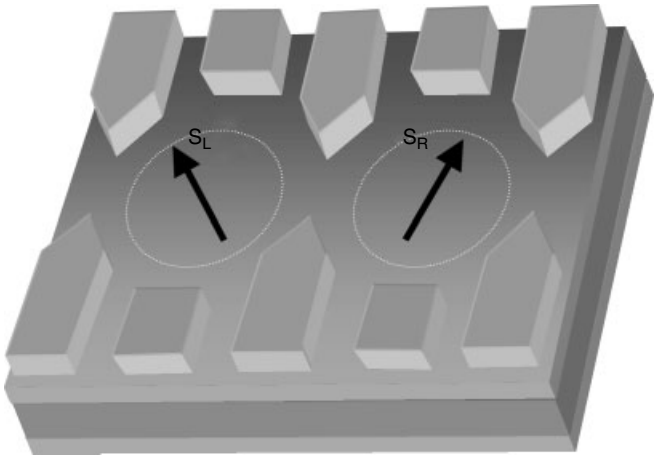

Figure 1. A double quantum dot. Top gates are set to an electrostatic voltage configuration that confines electrons in the two-dimensional electron gas (2DEG) below to the circular regions shown. Applying a negative voltage to the back gate, the dots can be depleted until they each contain only one single electron, each with an associated spin-1/2 operator $\mathbf{S}_{\mathrm{L(R)}}$ for the electron in the left (right) dot. The $|\uparrow\rangle$ and $|\downarrow\rangle$ spin-1/2 states of each electron provide a qubit (two-level quantum system).

quantum dots, as shown in Figure 1. Voltages applied to the top gates of such structures provide a confining potential for electrons in a two-dimensional electron gas (2DEG), below the surface. A negative voltage applied to a back-gate depletes the 2DEG locally, allowing the number of electrons in each dot to be reduced down to one (the single-electron regime). Advances in materials fabrication and gating techniques have now allowed for the realization of single electrons in single vertical (Tarucha *et al*., 1996) and gated lateral (Ciorga *et al*., 2000) dots, as well as double dots (Elzerman *et al*., 2003; Hayashi *et al*., 2003; Petta *et al*., 2004).

Initialization of all qubits in the quantum computer to the Zeeman ground state $|\uparrow\rangle = |0\rangle$ could be achieved by allowing all spins to reach thermal equilibrium at temperature T in the presence of a strong magnetic field B, such that $|g\mu_B B| > k_B T$, with g-factor $g < 0$, Bohr magneton μ_B, and Boltzmann's constant k_B (Loss and DiVincenzo, 1998). For example, assuming $g = -0.44$ (the bulk value for GaAs) and a temperature of $T = 100\,\text{mK}$, initialization with a probability $p > 99\%$ is achieved in a field of $B > 1\,\text{T}$. (For further initialization schemes, see Section 3.2.)

Once the qubits have been initialized to some state, they should remain in that state until a computation can be executed. In the absence of environmental coupling, the spins-1/2 of single electrons are intrinsic two-level systems, which cannot 'leak' into higher excited states. Additionally, since electron spins only couple to charge degrees of freedom indirectly through the spin-orbit (or hyperfine) interactions, they are relatively immune to fluctuations in the surrounding electronic environment.

Single-qubit operations in the Loss–DiVincenzo quantum computer could be carried out by varying the Zeeman splitting on each dot individually (Loss and DiVincenzo, 1998). It may be possible to do this through g-factor modulation (Salis *et al*., 2001), the inclusion of magnetic layers (Myers *et al*., 2005) (see also Figure 2), modification of the local Overhauser field due to hyperfine couplings (Burkard, Loss and DiVincenzo, 1999), or with nearby ferromagnetic dots (Loss and DiVincenzo, 1998). There are a number of alternate methods that could be used to perform single-qubit rotations (see Section 3.2).

Two-qubit operations would be performed within the Loss–DiVincenzo proposal by pulsing the exchange coupling between two neighboring qubit spins 'on' to a nonzero value ($J(t) = J_0 \neq 0$, $t \in \{-\tau_s/2 \ldots \tau_s/2\}$) for a switching time τ_s, then switching it 'off' ($J(t) = 0$, $t \notin \{-\tau_s/2 \ldots \tau_s/2\}$). This switching can be achieved by briefly lowering a center-gate barrier between neighboring electrons, resulting in an appreciable overlap of the electron wave functions (Loss and DiVincenzo, 1998), or alternatively, by pulsing the relative back-gate voltage of neighboring dots (Petta *et al*., 2005a) (see Section 4.3). Under such an operation (and in the absence of Zeeman or weaker spin-orbit or dipolar interactions), the effective two-spin Hamiltonian takes the form of an isotropic Heisenberg exchange term, given by (Loss and DiVincenzo, 1998; Burkard, Loss and DiVincenzo, 1999)

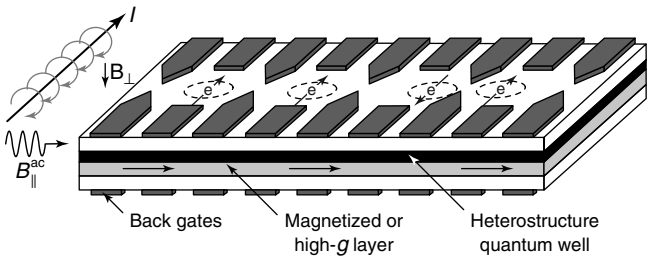

Figure 2. A series of exchange-coupled electron spins. Single-qubit operations could be performed in such a structure using electron-spin resonance (ESR), which would require an ac transverse magnetic field $B_{\parallel}^{ac}$, and a site-selective Zeeman splitting $g(x)\mu_B B_{\perp}$, which might be achieved through g-factor modulation or magnetic layers. Two-qubit operations would be performed by bringing two electrons into contact, introducing a nonzero wave function overlap and corresponding exchange coupling for some time (two electrons on the right). In the idle state, the electrons can be separated, eliminating the overlap and corresponding exchange coupling with exponential accuracy (two electrons on the left).

$$H_{ex}(t) = J(t)\mathbf{S}_L \cdot \mathbf{S}_R \tag{1}$$

where $\mathbf{S}_{L(R)}$ is the spin-1/2 operator for the electron in the left (right) dot, as shown in Figure 1. The Hamiltonian $H_{ex}(t)$ generates the unitary evolution $U(\phi) = \exp[-i\phi \mathbf{S}_L \cdot \mathbf{S}_R]$, where $\phi = \int J(t)dt/\hbar$. If the exchange is switched such that $\phi = \int J(t)dt/\hbar = J_0\tau_s/\hbar = \pi$, $U(\phi)$ exchanges the states of the two neighboring spins, that is, $U(\pi)\left|\mathbf{n}, \mathbf{n}'\right\rangle = \left|\mathbf{n}', \mathbf{n}\right\rangle$, where $\mathbf{n}$ and $\mathbf{n}'$ are two arbitrarily oriented unit vectors and $\left|\mathbf{n}, \mathbf{n}'\right\rangle$ indicates a simultaneous eigenstate of the two operators $\mathbf{S}_L \cdot \mathbf{n}$ and $\mathbf{S}_R \cdot \mathbf{n}'$. $U(\pi)$ implements the so-called SWAP operation. If the exchange is pulsed on for the shorter time $\tau_s/2$, the resulting operation $U(\pi/2) = (U(\pi))^{1/2}$ is known as the *square-root-of-SWAP* ($\sqrt{SWAP}$). The $\sqrt{\text{SWAP}}$ operation in combination with arbitrary single-qubit operations is sufficient for universal quantum computation (Barenco *et al*., 1995; Loss and DiVincenzo, 1998). The $\sqrt{\text{SWAP}}$ operation has now been successfully implemented in experiments involving two electrons confined to two neighboring quantum dots (as in Figure 1) (Petta *et al*., 2005a; Laird *et al*., 2006). Errors during the $\sqrt{\text{SWAP}}$ operation have been investigated due to nonadiabatic transitions to higher orbital states (Schliemann, Loss and MacDonald, 2001; Requist, Schliemann, Abanov and Loss, 2005), spin-orbit interaction (Bonesteel, Stepanenko and DiVincenzo, 2001; Burkard and Loss, 2002; Stepanenko *et al*., 2003), and hyperfine coupling to surrounding nuclear spins (Petta *et al*., 2005a; Coish and Loss, 2005;

Klauser, Coish and Loss, 2006; Taylor *et al*., 2006). The isotropic form of the exchange interaction given in equation (1) is not always valid. In realistic systems, a finite spin-orbit interaction leads to anisotropic terms which may cause additional errors, but could also be used to perform universal quantum computing with two-spin encoded qubits, in the absence of single-spin rotations (Bonesteel, Stepanenko and DiVincenzo, 2001; Lidar and Wu, 2002; Stepanenko and Bonesteel, 2004; Chutia, Friesen and Joynt, 2006) (see also Section 4.4 below for more on two-spin encoded qubits).

In the Loss–DiVincenzo proposal, readout could be performed using spin-to-charge conversion. This could be accomplished with a 'spin filter' (spin-selective tunneling) to leads or a neighboring dot, coupled with single-electron charge detection (see also Section 3.2).

3 SINGLE QUANTUM DOTS

There are many different types of quantum dot that can be manufactured, each with distinct characteristics. Gated lateral quantum dots (as shown in Figures 1 and 2) offer the benefit that their shape and size can be controlled to suit a particular study, and the tunnel coupling between pairs of these dots can be tuned in a straightforward manner: by raising or lowering the barrier between the dots. Gated vertical dots (Tarucha *et al*., 1996) are created by etching surrounding material to form a pillar structure, with vertical confinement provided by a double-barrier heterostructure. Vertical dots allow for the controlled fabrication of quantum dots with large level spacing, although tunability of the coupling in these structures is restricted due to the fabrication process. To resolve this issue, hybrid laterally coupled vertical double-quantum dots have been manufactured, in which the interdot tunnel coupling is controllable (Hatano, Stopa and Tarucha, 2005). Self-assembled quantum dots are yet another type of dot that can be used for quantum information processing. Self-assembled dots form spontaneously during epitaxial growth due to a lattice mismatch between the dot and substrate materials. These dots can be made with very large single-particle level spacing, but typically form at random locations, which makes controlled coupling through a tunnel junction difficult. Such dots can, however, potentially be coupled with optical cavity modes (Imamoğlu *et al*., 1999), and new techniques have now allowed the fabrication of cavities with modes that couple maximally directly at the positions of isolated dots (Badolato *et al*., 2005).

In the rest of this section, we focus on lateral quantum dots, as shown in Figures 1 and 2. After a brief review of charge and spin control in single quantum dots, we will address issues specific to double quantum dots in Section 4.

3.1 Charge control: Coulomb blockade

To ensure a single two-level system is available to be used as a qubit, it is practical to consider single isolated electron spins (with intrinsic spin 1/2) confined to single orbital levels. A natural first step to implementing the Loss–DiVincenzo proposal was therefore to demonstrate control over charging electron-by-electron in a single gated quantum dot. This is typically done by operating a quantum dot in the Coulomb-blockade regime, where the energy for the addition of an electron to the dot is larger than the energy that can be supplied by electrons in leads coupled to the dot. In this case, the charge on the quantum dot is conserved, and no electrons can tunnel onto or off of the dot. For a general review of Coulomb blockade phenomena and the characterization of many-electron states in single quantum dots, see Kouwenhoven, Austing and Tarucha (2001).

3.2 Spin control: initialization, operations, and readout

As mentioned in Section 2, initialization of all electron spins to the 'up' state $|\uparrow\rangle$ could be achieved by allowing all spins to equilibrate in a strong magnetic field. Depending on the particular architecture, this may take a long time or it may be inconvenient to have large magnetic fields in the region of the apparatus. Initialization could also be achieved through spin injection from a ferromagnet, as has been performed in bulk semiconductors (Fiederling *et al*., 1999; Ohno *et al*., 1999), with a spin-polarized current from a spin-filter device (Prinz and Hathaway, 1995; Prinz, 1998; Loss and DiVincenzo, 1998; DiVincenzo, 1999; Recher, Sukhorukov and Loss, 2000), or by optical pumping (Cortez *et al*., 2002; Shabaev, Efros, Gammon and Merkulov, 2003; Gywat *et al*., 2004; Bracker *et al*., 2005), which has now allowed the preparation of spin states with very high fidelity, in one case as high as 99.8% (Atature *et al*., 2006) [1].

Single-qubit operations could be performed in the Loss–DiVincenzo proposal whenever the Zeeman energy of the quantum-dot spins can be tuned locally, as mentioned in Section 2. Alternative single-qubit-rotation schemes may require global magnetic field gradients with pulsed magnetic and electric fields (Wu, Lidar and Friesen, 2004) or static magnetic, but ac electric fields (Tokura, van der Wiel, Obata and Tarucha, 2006), ESR (see Figure 2) or, in the presence of spin-orbit interaction, electric-dipole spin resonance (EDSR) techniques. EDSR has been analyzed in great detail for two-dimensional systems in theory (Rashba and Efros, 2003; Duckheim and Loss, 2006) and experiment (Kato, Myers,

Gossard and Awschalom, 2004), and can also be applied to lower-dimensional systems (quantum wires and quantum dots) (Levitov and Rashba, 2003; Golovach, Borhani and Loss, 2006), with the advantage that single-qubit operations could then be performed using fast all-electrical control. New experiments have now shown that it may be possible in practice to perform single-spin operations on spins in single quantum dots using ESR, as depicted in Figure 2 (Koppens *et al*., 2006).

In an alternative to the above proposals, it has recently been shown that arbitrary single-spin rotations could be performed with high fidelity in a quantum dot with a pulsed electric field, but a time-independent magnetic field gradient (Coish and Loss, 2006). This scheme would avoid 'heating' effects due to ac power dissipation (van der Wiel *et al*., 2006) since this scheme involves no ac electromagnetic fields, and could make use of large permanent magnetic field gradients ($\simeq 1\,\mathrm{T}/\mu\mathrm{m}$) arising from, for example, nanomagnets on the surface of semiconductors (Wróbel *et al*., 2004).

As mentioned in Section 2, quantum-dot spin readout can be performed using a spin filter. Experimentally, spin filters have been reported in the open (Potok, Folk, Marcus and Umansky, 2002) and Coulomb-blockade regimes (Folk, Potok, Marcus and Umansky, 2003), and have even been used to determine the longitudinal spin decay (T_1) time (Hanson *et al*., 2003; 2004) using an n-shot readout scheme, which has been analyzed in detail (Engel *et al*., 2004). A single-shot readout has also been demonstrated (Elzerman *et al*., 2004) and improved upon (Hanson *et al*., 2005). Non-invasive readout schemes using spin-to-charge conversion and quantum-point-contact (QPC) measurements have been used on two-spin encoded qubits (Johnson *et al*., 2005a; Petta *et al*., 2005a; Petta *et al*., 2005b; Johnson *et al*., 2005b) (see also Section 4.4).

To measure the transverse spin coherence time T_2, there have been proposals to perform ESR and detect the resulting resonance in stationary current (Engel and Loss, 2001), changes in the resistivity of a neighboring field-effect transistor (FET) (Martin, Mozyrsky and Jiang, 2003), optically (Gywat *et al*., 2004), or from current noise (Schaefers and Strunz, 2005). ESR in single quantum dots has not been observed until very recently, in part because it is challenging to generate high-frequency magnetic fields with sufficient power for single-spin manipulation without 'heating' electrons on the quantum dot or in the surrounding leads through the associated electric field (van der Wiel *et al*., 2006). Recent experiments overcome this problem (Koppens *et al*., 2006) by employing a double-quantum dot in the spin-blockade regime, where a smaller Zeeman splitting can be resolved, allowing the use of low-power ac magnetic fields (Burkard, 2006) (see also the discussion on spin blockade near the end of Section 5.2 below).

4 DOUBLE QUANTUM DOTS

Single qubits are the fundamental unit of quantum information in quantum computing. However, universal quantum computation still requires both single-qubit and two-qubit operations (Barenco, Deutsch, Ekert and Jozsa, 1995). In the Loss–DiVincenzo proposal, two-qubit gates are performed with exchange-coupled electron spins confined to two neighboring quantum dots (double dots). Double dots are also important for two-electron encoded qubits (Levy, 2002), in which qubits are encoded into a two-dimensional pseudospin-1/2 subspace of a four-dimensional two-electron spin system.

In this section, we discuss characterization and manipulation techniques that are commonly used to extract microscopic parameters of double quantum dots. In Section 4.1, we review the charge stability diagram and illustrate its connection to a commonly used microscopic model Hamiltonian. In Section 4.2, we review work on the coherent coupling of double quantum dots, which is required to generate a large exchange interaction for two-qubit gating. In Section 4.3, we discuss the use of double quantum dots as two-qubit gates, and in Section 4.4 we review some work on using double quantum dots to control single 'encoded' qubits (Levy, 2002), a topic which has now come into vogue (Petta *et al*., 2005a; Taylor *et al*., 2005; Burkard and Imamoglu, 2006; Hanson and Burkard, 2007).

4.1 The double-dot charge stability diagram

Just as transport through a single quantum dot and Coulomb blockade phenomena give information about the orbital level spacing, charging energy, and spin states of single quantum dots, similar studies can be carried out on double quantum dots. Whereas for single dots, transport phenomena are typically understood in terms of one-dimensional plots of conductance versus gate voltage, the primary tool used to understand double quantum dots is the double-dot charge stability diagram. The stability diagram is a two-dimensional plot of current or differential conductance through the double dot or through a neighboring QPC, given as a function of two independent back-gate voltages (one applied locally to each dot). The plot differentiates regions where the double-dot ground state has a charge configuration (N_1, N_2), for various N_1, N_2, where N_1 is the number of charges on the left dot and N_2 is the number of charges on the right. Transport through double quantum dots and the relevant charge stability diagram have been discussed thoroughly in (van der Wiel *et al*., 2003). In the rest of this section, we review some features of the double-dot stability diagram with an emphasis on the connection to a model Hamiltonian that is commonly used in the literature (Klimeck, Chen and Datta, 1994; Pals

and MacKinnon, 1996; Golden and Halperin, 1996; Ziegler, Bruder and Schoeller, 2000).

An isolated double quantum dot is described by the Hamiltonian

$$H_{\mathrm{dd}} = H_{\mathrm{C}} + H_{\mathrm{T}} + H_{\mathrm{S}} \tag{2}$$

where H_{C} gives the single-particle and interparticle charging energies due to Coulomb interaction as well as the orbital energy, H_{T} is the interdot tunneling term due to a finite overlap of dot-localized single-particle wave functions, which ultimately gives rise to exchange, and H_{S} contains explicitly spin-dependent terms, which may include spin-orbit interaction, dipole–dipole interaction, and the contact hyperfine interaction between the confined electron spins and nuclear spins in the surrounding lattice.

There are several approaches that can be taken to writing the various components of the double-dot Hamiltonian H_{dd}, corresponding to several degrees of microscopic detail. In the simplest form, the Hubbard model, details of the electron wave functions are neglected and the Coulomb interaction is modeled by on-site and nearest-neighbor terms. Since this description relies only on very few parameters, it is the most commonly used in the literature on transport phenomena through quantum dots. The shape of the confining potential, quantum-dot localized wave functions, and form of the Coulomb interaction may become important in certain circumstances, in which case it is more appropriate to apply either the Heitler–London method (which neglects doubly occupied dot levels), or the Hund–Mulliken method, which includes the effects of double-occupancy. These methods predict, for instance, a variation of the interdot exchange interaction through zero with increasing out-of-plane magnetic field (Burkard, Loss and DiVincenzo, 1999). Experimentally, it has been confirmed that the exchange coupling can be tuned with an out-of-plane magnetic field in single vertical (Fujisawa *et al*., 2002) and single lateral quantum dots (Zumbühl, Marcus, Hanson and Gossard, 2004), which behave effectively as double-dot structures. Here we ignore these effects and focus on the simplest Hubbard model that reproduces much of the double-dot physics that can be seen in transport phenomena.

We model the Coulomb interaction with simple on-site ($U_{1(2)}$ for the left (right) dot) and nearest-neighbor (U') repulsion. The single-particle charging energy is given in terms of a local dot potential $V_{1(2)}$. The charging Hamiltonian is then

$$H_{\mathrm{C}} = \frac{1}{2}\sum_{l} U_l N_l\,(N_l - 1) + U' N_1 N_2 - |e| \sum_{l} V_l N_l + \sum_{kl} \epsilon_{lk} n_{lk} \tag{3}$$

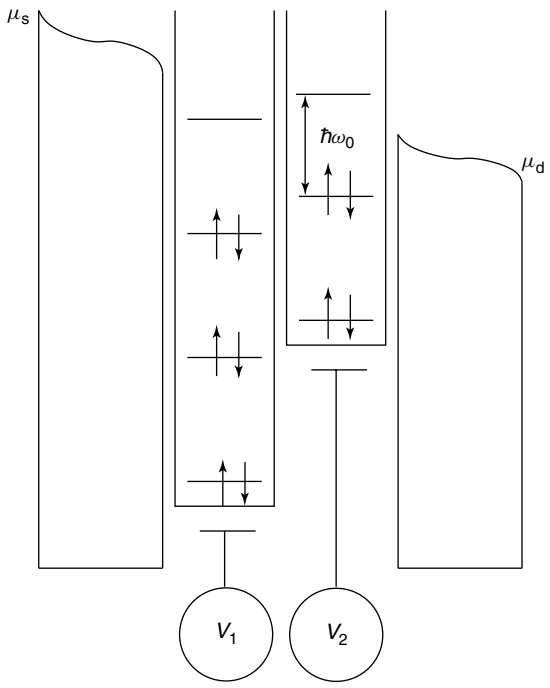

Figure 3. Ground state configuration for a double quantum dot with large orbital and charging energies, and negligible dot-lead and interdot coupling. $\mu_{\mathrm{s(d)}}$ is the source (drain) chemical potential, $V_{1(2)}$ is the left (right) local dot potential, which is related to applied gate potentials by a linear transformation (see equation (5), below), and both dots are assumed to have the same uniform level spacing $\hbar\omega_0$.

where $N_l = \sum_k n_{lk}$ counts the total number of electrons in dot l, with $n_{lk} = \sum_\sigma d^\dagger_{lk\sigma} d_{lk\sigma}$, and here $d_{lk\sigma}$ annihilates an electron on dot l, in orbital k, with spin σ. ϵ_{lk} is the energy of single-particle orbital level k in dot l, which gives rise to the typical orbital level spacing $\epsilon_{lk+1} - \epsilon_{lk} \approx \hbar\omega_0$ (see Figure 3).

Within the capacitive charging model described by the equivalent circuit in the inset of Figure 4(a), the microscopic charging energies are related to capacitances by (Ziegler, Bruder and Schoeller, 2000; van der Wiel *et al*., 2003)

$$U_l = \frac{C_1 C_2}{C_1 C_2 - C_{\mathrm{m}}^2}\frac{e^2}{C_l},\quad U' = \frac{2e^2 C_{\mathrm{m}}}{C_1 C_2 - C_{\mathrm{m}}^2} \tag{4}$$

where $C_1 = C_{\mathrm{s}} + C_{\mathrm{m}} + C_{\mathrm{g1}}$, $C_2 = C_{\mathrm{d}} + C_{\mathrm{m}} + C_{\mathrm{g2}}$, and all capacitances are defined in the inset of Figure 4(a). In experiments, the local quantum-dot potentials $V_{1,2}$ are controlled indirectly in terms of gate voltages $V_{\mathrm{g1,2}}$, which are capacitively coupled to the dots through gate capacitances $C_{\mathrm{g1,2}}$. For fixed quantum-dot charges $(Q_1, Q_2) = -|e|\,(N_1, N_2) =$ const., differences in the dot voltages ΔV_1 and ΔV_2 are related to differences in the gate voltages ΔV_{g1} and ΔV_{g2} through (Ziegler, Bruder and Schoeller, 2000; van der Wiel

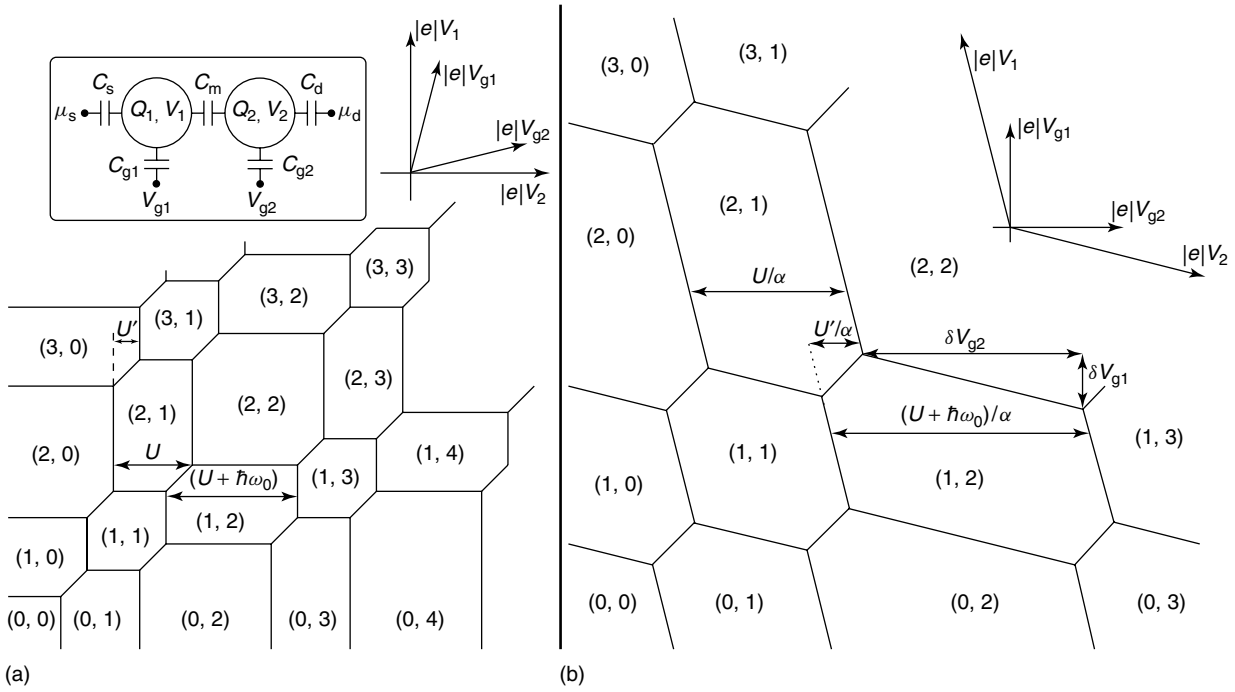

Figure 4. Stability diagram plotted in terms of (a) local dot potentials $V_{1,2}$ and (b) applied gate potentials $V_{g1,2}$, with on-site charging energies $U_l = U$, $l = 1, 2$, nearest-neighbor charging energy U', and dot orbital level spacing $\hbar\omega_0$ satisfying $U{:}\hbar\omega_0{:}U' = 3{:}2{:}1$. In addition, for (b) we have assumed the voltage scaling factors are the same for both dots, and are given by $\alpha_1 = \alpha_2 = \alpha = 1/2$. (a) inset: capacitive charging model for a double quantum dot, indicating the source (drain) chemical potential $\mu_{s(d)}$, the charge on the left (right) dot $Q_{1(2)}$, the capacitances to source (drain) $C_{s(d)}$, the mutual capacitance C_m, and gate capacitances $C_{g1,2}$. (b) Horizontal lines in the $|e|\,V_{1(2)}$ plane become skewed with slope $\delta V_{g1}/\delta V_{g2} = -C_m C_{g2}/C_2 C_{g1}$ when plotted versus $|e|\,V_{g1(2)}$.

et al., 2003)

$$\begin{pmatrix} C_1 & -C_m \\ -C_m & C_2 \end{pmatrix} \begin{pmatrix} \Delta V_1 \\ \Delta V_2 \end{pmatrix} = \begin{pmatrix} C_{g1}\Delta V_{g1} \\ C_{g2}\Delta V_{g2} \end{pmatrix} \tag{5}$$

The double-dot stability diagram can then be given equivalently as a two-dimensional plot with energy axes $|e|\,V_1$, $|e|\,V_2$, or with axes $|e|\,V_{g1}$, $|e|\,V_{g2}$, which are skewed and stretched with respect to the original axes according to the transformation given in equation (5). The end effect is that parallel horizontal (vertical) lines in the $|e|\,V_{1(2)}$ plane separated by a distance $dV_{1(2)}$ transform to skewed parallel lines, separated by $dV_{g1(2)} = dV_{1(2)}/\alpha_{1(2)}$ along the vertical (horizontal) of the new coordinate system, where (see Figure 4).

$$\alpha_l = \frac{C_{gl}}{C_l}, \quad l = 1, 2 \tag{6}$$

Additionally, horizontal lines in the $|e|\,V_{1(2)}$ plane become skewed with a slope $\delta V_{g1}/\delta V_{g2} = -C_m C_{g2}/C_2 C_{g1}$ (see Figure 4b), and vertical lines are skewed with slope $\delta V_{g1}/\delta V_{g2} = -C_1 C_{g2}/C_m C_{g1}$.

The Hamiltonian in equation (3) conserves the number of electrons on each dot: $[H_C, N_l] = 0$, so we label the ground state by the two dot occupation numbers, (N_1, N_2), and indicate where each configuration is the ground state in Figure 4 for equivalent quantum dots that satisfy $\alpha_1 = \alpha_2 = \alpha = 1/2$, $U_1 = U_2 = U$, $\epsilon_{lk+1} - \epsilon_{lk} = \hbar\omega_0$ for all k, l, and $U : \hbar\omega_0 : U' = 3 : 2 : 1$. The charge stability diagram is described by a 'honeycomb' of irregular hexagons with dimensions that are determined by three typical energy scales: (i) The on-site repulsion U, (ii) the nearest-neighbor repulsion U', and (iii) the typical orbital energy $\hbar\omega_0$. Figure 4 assumes a ground state electron filling as shown in Figure 3, with constant orbital energy $\hbar\omega_0$. In this case, the orbital energy appears in the dimensions of only every second honeycomb cell of the stability diagram, along the horizontal or vertical direction, since the spin-degenerate orbital states fill with two electrons at a time according to the Pauli principle. This even–odd behavior may not be visible in dots of high symmetry, where the orbital levels are manifold degenerate (such an orbital degeneracy may make it difficult to generate a well-defined two-level system for electron spins in carbon nanotubes or gated graphene, although there are potential solutions to this problem (Trauzettel, Bulaev, Loss and Burkard, 2007)). Alternatively, the absence of an even–odd effect in low-symmetry single dots has previously been attributed to the absence of spin degeneracy due to

many-body effects (Stewart *et al*., 1997; Fujisawa, Tokura and Hirayama, 2001; van der Wiel *et al*., 2003).

Each vertex of a honeycomb cell corresponds to a triple-point, where three double-dot charge states are simultaneously degenerate. For a double dot connected to source and drain leads at low temperature, and in the absence of relaxation or photo-assisted tunneling processes, it is only at these points where resonant sequential transport can occur, through shuttling processes of the form $(0, 0) \rightarrow (1, 0) \rightarrow (0, 1) \rightarrow (0, 0)$. This picture changes when a strong interdot tunnel coupling H_{T} is considered in addition.

4.2 Molecular states in double dots

Molecule-like states have been observed and studied in detail in two-electron single vertical (Fujisawa *et al*., 2002) and lateral quantum dots (Zumbühl, Marcus, Hanson and Gossard, 2004) (the latter behave as an effective double-dot structure, showing good agreement with theory (Golovach and Loss, 2004)). Evidence of molecular states forming also in double quantum dots due to a strong interdot tunnel coupling has been found in a variety of systems (Schmidt *et al*., 1997; Schedelbeck, Wegscheider, Bichler and Abstreiter, 1997; Blick *et al*., 1998; Brodsky *et al*., 2000; Bayer *et al*., 2001; Ota *et al*., 2005; Hüttel *et al*., 2005; Fasth, Fuhrer, Bjork and Samuelson, 2005; Mason, Biercuk and Marcus, 2004; Biercuk *et al*., 2005; Graeber *et al*., 2006). For example, molecular states have been observed in many-electron gated quantum dots in linear transport (Blick *et al*., 1998) (solid lines of Figure 5b) and transport through excited states (Hüttel *et al*., 2005) (dashed lines in Figure 5b). In addition, molecular states have been observed in vertical-lateral gated double-quantum dots (Hatano, Stopa and Tarucha, 2005), gated dots formed in quantum wires (Fasth, Fuhrer, Bjork and Samuelson, 2005) and gated carbon-nanotube double dots (Mason, Biercuk and Marcus, 2004; Biercuk *et al*., 2005; Graeber *et al*., 2006). A large interdot tunnel coupling is essential for generating a large exchange interaction J (see equation (23) below), and is therefore very important for the implementation of fast two-qubit gates in the Loss–DiVincenzo proposal.

In this section, we analyze changes to the double-dot stability diagram that occur due to the interdot tunneling term H_{T}. We focus on the relevant regime for quantum computing, where only a single orbital state is available for occupation on each quantum dot (the lower-left region of Figure 4a and b). In the subspace of these lowest dot orbital states, H_{T} is given by:

$$H_{\mathrm{T}} = t_{12} \sum_{\sigma} d_{1\sigma}^{\dagger} d_{2\sigma} + \mathrm{H.c.} \tag{7}$$

where t_{12} is the tunneling amplitude between the two dots, and $d_{l\sigma}$, $l = 1, 2$, annihilates an electron in the lowest single-particle orbital state localized on quantum dot l with spin σ.

When the double dot is occupied by only $N = 0, 1$ electrons and is coupled weakly to leads, an explicit expression can be found for the current passing through a sequentially coupled double dot, as shown in Figure 5(a) (Ziegler, Bruder and Schoeller, 2000; Graeber *et al*., 2006). It is straightforward to diagonalize $H_{\mathrm{C}} + H_{\mathrm{T}}$ in the subspace of $N = 1$ electrons on the quantum dot. This gives the (spin-degenerate) eigenenergies and corresponding eigenvectors:

$$E_{\pm}(\Delta, \epsilon) = -\frac{1}{\sqrt{2}} \left(\Delta \pm \sqrt{\epsilon^2 + 2t_{12}^2} \right) \tag{8}$$

$$|E_{\pm}\rangle = \cos\left(\frac{\theta_{\pm}}{2}\right) |1, 0\rangle + \sin\left(\frac{\theta_{\pm}}{2}\right) |0, 1\rangle \tag{9}$$

$$\tan\left(\frac{\theta_{\pm}}{2}\right) = \frac{\epsilon \mp \sqrt{\epsilon^2 + 2t_{12}^2}}{\sqrt{2} t_{12}} \tag{10}$$

Here, $E_{\pm}(\Delta, \epsilon)$ is written in terms of new energy coordinates ϵ, Δ, which are related to the old (voltage) coordinates through a rotation of the axes by 45° (see also Figure 5b):

$$\begin{pmatrix} \Delta \\ \epsilon \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix} \begin{pmatrix} |e| V_1 \\ |e| V_2 \end{pmatrix} \tag{11}$$

We then define double-dot chemical potentials:

$$\mu_{\pm}(\Delta, \epsilon) = E_{\pm}(\Delta, \epsilon) - E_0 \tag{12}$$

where $E_0 = 0$ is the energy of the $(0, 0)$ charge configuration. In the presence of a strong tunnel coupling, the eigenstates of the double dot are no longer labeled separately by the quantum numbers N_1, N_2. Instead, the sum $N = N_1 + N_2$ is conserved. If we add to H_{dd} the double-dot-lead coupling Hamiltonian $H_{\mathrm{dd-}L} = \sum_{k\sigma} t_{\mathrm{s}} c_{\mathrm{s}k\sigma}^{\dagger} d_{1\sigma} + t_{\mathrm{d}} c_{\mathrm{d}k\sigma}^{\dagger} d_{2\sigma} + \mathrm{H.c.}$, where $c_{\mathrm{s(d)}k\sigma}^{\dagger}$ creates an electron in the source (drain), in orbital k with spin σ, then N can fluctuate between 1 and 0 if the double-dot and lead chemical potentials are equal. We identify double-dot sequential-tunneling processes as those that change the total charge on the double-dot by one: $N \rightarrow N \pm 1$ (Golovach and Loss, 2004). One can evaluate golden-rule rates for all sequential-tunneling processes, taking the dot-lead coupling $H_{\mathrm{dd-L}}$ as a perturbation to obtain the stationary current from a standard Pauli master equation (the Pauli master equation is valid for sufficiently high temperature, $k_{\mathrm{B}}T > \Gamma_{\mathrm{s(d)}}$, so that off-diagonal elements can be ignored in the double-dot density matrix). For weak dot-lead coupling, at low temperature $k_{\mathrm{B}}T < \hbar\omega_0$, and at zero bias ($\mu = \mu_s = \mu_d + \Delta\mu$, with $\Delta\mu \rightarrow 0$), transport occurs only through the $N = 1$ ground state, with chemical

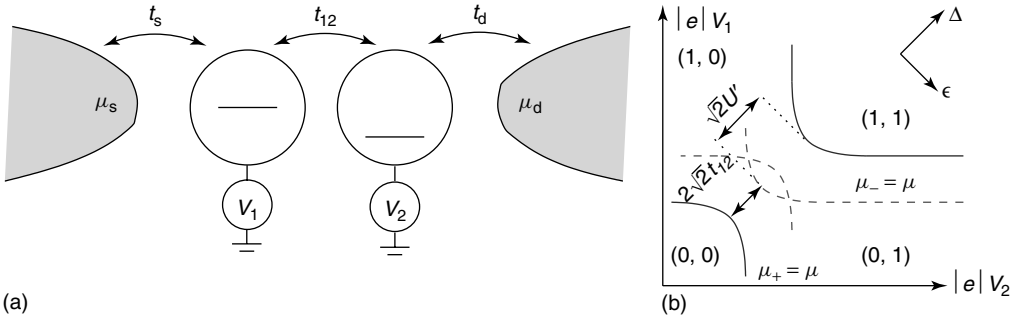

Figure 5. (a) A tunnel-coupled double quantum dot, with tunneling amplitude t_{12}. The source and drain leads, at chemical potentials μ_s and μ_d, are connected to the left and right dots through tunnel barriers with tunneling amplitudes t_s and t_d, respectively. The left and right dots are set to local potentials V_1 and V_2. (b) Modification of the stability diagram in the case of a significant tunnel coupling t_{12}. To generate this figure we have chosen the ratio of tunnel coupling to the mutual (nearest-neighbor) charging energy to be $t_{12}/U' \approx 1/5$. At solid lines, transport occurs via the double-dot ground state $|E_+\rangle$ and at dashed lines additional transport can occur through the first excited state $|E_-\rangle$ (see equations (9) and (10) below).

potential μ_+. The differential conductance near the $N = 0, 1$ boundary is then given by

$$\frac{\mathrm{d}I}{\mathrm{d}(\Delta\mu)} = |e|\,\Gamma\left(\frac{-2f'(\mu_+)}{1+f(\mu_+)}\right)$$

$$\Gamma = \frac{\sin^2(\theta_+)\,\Gamma_s\Gamma_d}{4\left(\cos^2\left(\frac{\theta_+}{2}\right)\Gamma_s + \sin^2\left(\frac{\theta_+}{2}\right)\Gamma_d\right)} \qquad (13)$$

where $f(E) = 1\Big/\left[1+\exp\left(\frac{E-\mu}{k_BT}\right)\right]$ is the Fermi function at chemical potential μ and temperature T, $f'(E) = \mathrm{d}f(E)/\mathrm{d}E$, and $\Gamma_{s(d)} = \frac{2\pi\nu}{\hbar}\left|t_{s(d)}\right|^2$ is the tunneling rate to the source (drain) with a lead density of states per spin ν at the Fermi energy. If spin degeneracy is lifted, the quantity in brackets in equation (13) is replaced by the familiar term $-f'(\mu_+) = 1\Big/\left[4k_BT\cosh^2\left(\frac{\mu_+-\mu}{2k_BT}\right)\right]$ (Beenakker, 1991). The differential conductance (equation (13)) reaches a maximum near the point where the double-dot chemical potential matches the lead chemical potential, $\mu_+(\Delta,\epsilon) = \mu$, which we indicate with a solid line in Figure 5(b). Transport through the excited state can occur where $\mu_-(\Delta,\epsilon) = \mu$, and when the bias $\Delta\mu = \mu_s - \mu_d$ or temperature T are sufficiently large to generate a significant population in the excited state $|E_-\rangle$. Dashed lines indicate where $\mu_-(\Delta,\epsilon) = \mu$ in Figure 5(b).

There are several qualitative changes to the double-dot stability diagram that take place in the presence of strong tunnel coupling. First, the number of electrons on each dot is not conserved individually. Instead, the sum $N = N_1 + N_2$ is conserved, which means that there are no longer lines separating, for example, the (1,0) and (0,1) states in Figure 5(b). Second, sequential-tunneling processes allow current to be transported through the double dot along the length of the 'wings' that define the boundaries between N and $N \pm 1$-electron ground states. This is in contrast to the case where t_{12} is weak, in which resonant sequential transport can only occur at triple points, where the shuttling processes of the type $(0,0) \to (1,0) \to (0,1) \to (0,0)$ are allowed by energy conservation.

4.3 Two-qubit gates in double quantum dots

The $\sqrt{\mathrm{SWAP}}$ operation described in Section 2 requires significant control of the exchange coupling J. The value of J can be controlled by raising/lowering the interdot barrier, thus changing the tunnel coupling t_{12} (Loss and DiVincenzo, 1998), or with an out-of-plane magnetic field or weak in-plane electric field (Burkard, Loss and DiVincenzo, 1999). More recently, experiments have controlled J by varying the back-gate voltages on two neighboring quantum dots through a large parameter regime, independently (Petta *et al*., 2005a). Here we discuss this last method to control J, which has been analyzed in several recent papers (Petta *et al*., 2005b; Coish and Loss, 2005; Taylor *et al*., 2006; Stopa and Marcus, 2006).

We consider a double quantum dot in the region of the charge stability diagram indicated in the lower inset of Figure 6. Specifically, we consider the regime of gate voltages where the double dot contains $N = 2$ electrons near the degeneracy point of the $(1,1)$ and $(0,2)$ charge states, and aim to diagonalize the Hamiltonian $H_C + H_T$ in the basis of three spin triplets and two relevant singlets:

$$|S(0,2)\rangle = d^\dagger_{2\downarrow}d^\dagger_{2\uparrow}\,|\mathrm{vac.}\rangle \qquad (14)$$

$$|S(1,1)\rangle = \frac{1}{\sqrt{2}}\left(d^\dagger_{2\downarrow}d^\dagger_{1\uparrow} - d^\dagger_{2\uparrow}d^\dagger_{1\downarrow}\right)|\mathrm{vac.}\rangle \qquad (15)$$

$$|T_0\rangle = \frac{1}{\sqrt{2}}\left(d^\dagger_{2\downarrow}d^\dagger_{1\uparrow} + d^\dagger_{2\uparrow}d^\dagger_{1\downarrow}\right)|\mathrm{vac.}\rangle \qquad (16)$$

$$|T_+\rangle = d^\dagger_{2\uparrow} d^\dagger_{1\uparrow} |\text{vac.}\rangle \tag{17}$$

$$|T_-\rangle = d^\dagger_{2\downarrow} d^\dagger_{1\downarrow} |\text{vac.}\rangle \tag{18}$$

In the absence of additional spin-dependent terms, the triplets are degenerate, with energy $E_{\text{Triplet}} = E_{(1,1)} = -\sqrt{2}\Delta'$, whereas the two singlet states have energies and associated eigenvectors

$$E^{\pm}_{\text{Singlet}} = E_{\text{Triplet}} - \frac{1}{\sqrt{2}}\left(\epsilon' \pm \sqrt{(\epsilon')^2 + 4t_{12}^2}\right) \tag{19}$$

$$\left|E^{\pm}_{\text{Singlet}}\right\rangle = \cos\left(\frac{\theta^S_{\pm}}{2}\right)|S(1,1)\rangle + \sin\left(\frac{\theta^S_{\pm}}{2}\right)|S(0,2)\rangle \tag{20}$$

$$\tan\left(\frac{\theta^S_{\pm}}{2}\right) = \frac{\epsilon' \mp \sqrt{(\epsilon')^2 + 4t_{12}^2}}{2t_{12}} \tag{21}$$

Here, Δ' and ϵ' are related to the previous coordinates (Δ, ϵ) through a simple translation of the origin:

$$\begin{pmatrix}\Delta' \\ \epsilon'\end{pmatrix} = \begin{pmatrix}\Delta \\ \epsilon\end{pmatrix} + \frac{1}{\sqrt{2}}\begin{pmatrix}-U' \\ U' - U\end{pmatrix} \tag{22}$$

This gives rise to the Heisenberg exchange for large negative ϵ' (from equation (19)):

$$J(\epsilon') = E_{\text{Triplet}} - E^{+}_{\text{Singlet}} \approx \frac{\sqrt{2}t_{12}^2}{|\epsilon'|}, \quad \epsilon' < 0, \quad |\epsilon'| \gg 2t_{12} \tag{23}$$

By pulsing $\epsilon' = \epsilon'(t)$, the exchange $J(\epsilon'(t))$ can be pulsed on and off again in order to implement the $\sqrt{\text{SWAP}}$ operation, as described in Section 2 (see the inset of Figure 6). This operation has now been achieved experimentally with a gating time on the order of 180 ps (Petta *et al*., 2005a), in good agreement with the predictions in (Burkard, Loss and DiVincenzo, 1999) for an achievable switching time.

4.4 Initialization of two-spin encoded qubits

Fluctuations in a nuclear spin environment can lead to rapid decoherence of single-electron spin states due to the contact hyperfine interaction (see Section 5). The effects of these fluctuations can be reduced, in part, by considering a qubit encoded in two-electron singlet $|0\rangle = |S(1,1)\rangle$ and triplet states $|1\rangle = |T_0\rangle$, as defined in equations (15) and (16). A qubit encoded in this two-dimensional subspace would be immune to global magnetic field fluctuations, and is then only susceptible to fluctuations in the difference of the magnetic field on the two dots. With this encoding scheme, the qubit energy splitting would be provided through the exchange coupling (equation (23)), and single-qubit rotations

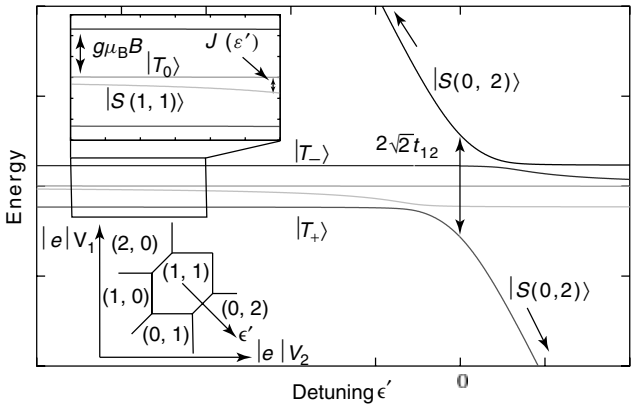

Figure 6. Energy level spectrum for two electrons in the two lowest orbital states of a double quantum dot. The triplet states $|T_\pm\rangle$ are split off from $|T_0\rangle$ and $|S(1,1)\rangle$ by the Zeeman splitting $g\mu_B B$ (see the upper inset). The exchange coupling J (which gives the splitting between $|T_0\rangle$ and $|S(1,1)\rangle$) can be changed by varying the detuning ϵ' (pictured in the lower inset).

could be performed using an inhomogeneous magnetic field (Levy, 2002). Two-qubit operations in this scheme could be performed, for example, using capacitive coupling due to the relative charge distributions of the triplet and singlet states in neighboring double dots (Taylor *et al*., 2005), although the difference in these charge distributions can lead to additional dephasing due to fluctuations in the electrical environment (Coish and Loss, 2005) (see also Section 5, below). An alternative scheme to couple such encoded qubits over long distances with optical cavity modes has also been proposed (Burkard and Imamoglu, 2006). One additional advantage of the two-spin encoded qubit scheme is that adiabatic tuning of the gate voltages can be used to initialize and read out information stored in the singlet–triplet basis (Johnson *et al*., 2005a; Petta *et al*., 2005a). We discuss this initialization scheme in the rest of this section.

We consider the singlet ground state $\left|E^{+}_{\text{Singlet}}\right\rangle$, given by equations (20) and (21). For large positive detuning, $|\epsilon'| \gg t_{12}, \epsilon' > 0$, the mixing angle in equation (21) is $\theta^S_+ \approx \pi$ and the singlet ground state is approximately given by $|S(0,2)\rangle$. For large negative detuning $|\epsilon'| \gg t_{12}, \epsilon' < 0$, we find $\theta^S_+ \approx 0$ and the lowest-energy singlet is instead given by $|S(1,1)\rangle$ (see Figure 6). If the two-electron system is allowed to relax to its ground state $|S(0,2)\rangle$ at large positive detuning ϵ' and the detuning is then varied adiabatically slowly to large negative values, the encoded qubit can be initialized to the state $|0\rangle = |S(1,1)\rangle$ (see Figure 6 and insets). It is a straightforward exercise to estimate the error in such an operation for a two-dimensional Hamiltonian.

For a linear ramp of ϵ' over an infinite interval (i.e., $\epsilon' = (\Delta\epsilon/\tau_{\text{sw}})\,t$, $t = -\infty \ldots \infty$ with characteristic switching time τ_{sw} to sweep over an interval $\Delta\epsilon$), the result of Zener,

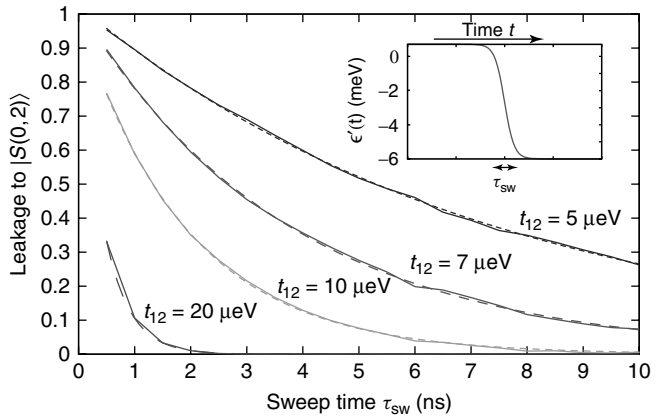

Figure 7. Leakage (the occupation probability of the state $|S(0,2)\rangle$ at the end of the sweep) due to nonadiabatic transitions after sweeping from $\epsilon' = 0.7\,\text{meV}$ to $\epsilon' = -6\,\text{meV}$. Leakage is given as a function of the characteristic sweep time τ_{sw}, where $\epsilon'(t) = \epsilon_0 - \frac{\Delta\epsilon}{2}\tanh(2t/\tau_{\text{sw}})$, with $\epsilon_0 = -2.65\,\text{meV}$ and $\Delta\epsilon = 6.7\,\text{meV}$. We show results for $t_{12} = 5, 7, 10, 20\,\mu\text{eV}$. Solid lines show the results of numerical integration of the Schrödinger equation and dashed lines give exponential fits, which decay with the time constants τ_{fit}, given in Table 1.

for the nonadiabatic Landau–Zener transition probability is (Zener, 1932)

$$P = \exp\left(-\frac{\tau_{\text{sw}}}{\tau_{LZ}}\right), \quad \tau_{LZ} = \frac{\hbar\sqrt{2}\Delta\epsilon}{4\pi t_{12}^2} \tag{24}$$

Here, the Landau–Zener tunneling probability is controlled in terms of two timescales: the switching time τ_{sw} for a typical range of $\Delta\epsilon$ and the Landau–Zener time constant τ_{LZ}, which has a strong dependence ($\propto 1/t_{12}^2$) on the interdot tunnel coupling. For a realistic voltage pulse, ϵ' is swept over a finite interval, and the pulse shape, in general, will not be linear for the entire sweep. Performing an analysis similar to that used for single-spin gates (Schliemann, Loss and MacDonald, 2001; Requist, Schliemann, Abanov and Loss, 2005) for this case, one can perform a numerical integration of the time-dependent Schrödinger equation in the subspace formed by the two singlets for an arbitrary pulse shape. We have done this for a pulse of the form $\epsilon'(t) = \epsilon_0 - \frac{\Delta\epsilon}{2}\tanh(2t/\tau_{\text{sw}})$, $t = -5\tau_{\text{sw}} \ldots 5\tau_{\text{sw}}$ [2], where we find an approximately exponential dependence of P on the switching time τ_{sw} (see Figure 7). Fitting to this exponential dependence, we find a time constant τ_{fit} analogous to the Landau–Zener time τ_{LZ}. The time constants τ_{LZ} (from equation (24)) and τ_{fit} from the numerical data in Figure 7 are compared in Table 1 for various values of the interdot tunnel coupling t_{12}. The results of Figure 7 and Table 1 suggest that (for this set of parameters) adiabatic switching for initialization or readout on a timescale of $\tau_{\text{sw}} \lesssim 1\,\text{ns}$ can only be performed without significant error if the tunnel coupling t_{12} is made larger than $t_{12} > 20\,\mu\text{eV}$. It is important to note that this analysis ignores additional effects due to magnetic-field inhomogeneities, spin-orbit coupling, or the hyperfine interaction, all of which can lead to additional singlet–triplet anticrossings (see Section 5.2, below) and hence, to additional initialization or readout errors.

Table 1. Landau–Zener time constant τ_{LZ} for a linear ramp of ϵ' and the time constant τ_{fit} for fits to numerically evaluated data at various values of the tunnel coupling t_{12}.

t_{12} (μeV)	τ_{LZ} (ns)	τ_{fit} (ns)
5	20	7.4
7	10	3.8
10	4.9	1.9
20	1.2	0.43

5 DECOHERENCE

Decoherence is the process by which information stored in a quantum bit is lost. There are two timescales used to describe decoherence processes for a spin that decays exponentially in the presence of an applied magnetic field. T_1 is the longitudinal spin decay time, or spin-flip time, which describes the timescale for random spin flips: $|\uparrow\rangle \rightarrow |\downarrow\rangle$. T_2, the transverse spin decay time, describes the decay of a superposition state $a|\uparrow\rangle + b|\downarrow\rangle$. Both of these timescales are important for quantum computing, since both effects lead to qubit errors.

An experiment performed on an ensemble of systems with different environments can lead to additional decoherence, beyond that described by the 'intrinsic' T_2 time (Slichter, 1980). For such an experiment, the ensemble-averaged transverse spin decay time is therefore often denoted T_2^* to distinguish it from the single-spin decay time. Other symbols such as τ_c (the correlation time) and T_{M} (the magnetization envelope decay time) are often used to distinguish decay that is nonexponential.

For a quantum-dot-confined electron-spin state to decay, it is necessary for the spin to couple in some way to fluctuations in the environment. There are two important sources of this coupling for electron spins in quantum dots. First, the spin-orbit interaction couples electron spin states to their orbital states, and therefore makes spins indirectly sensitive to fluctuations in the electric environment. Second, the Fermi contact hyperfine interaction between electrons and surrounding nuclear spins in the host material can lead to rapid decay if fluctuations in the nuclear spin environment

are not properly controlled. In the rest of this section we discuss recent progress in understanding decoherence due to these two coupling mechanisms.

5.1 Spin-orbit interaction

For a 2DEG formed in GaAs, the spin-orbit interaction is given in terms of two terms:

$$H_{\mathrm{SO}} = \alpha\left(p_x\sigma_y - p_y\sigma_x\right) + \beta\left(p_y\sigma_y - p_x\sigma_x\right) + O\left(|\mathbf{p}|^3\right) \tag{25}$$

where $\sigma_{x,y}$ are Pauli matrices and $\mathbf{p} = (p_x, p_y)$ is the momentum operator in the plane of the 2DEG. The first term, proportional to α, is the Rashba (or structure-inversion-asymmetry) spin-orbit coupling term. The Rashba term is due to asymmetry in the confining potential and can therefore be tuned to some degree with applied gates. The second term, proportional to β, is the Dresselhaus (bulk-inversion-asymmetry) term, and is due to the fact that GaAs, which has a zinc-blende lattice, has no center of inversion symmetry. Corrections to this spin-orbit Hamiltonian of order $|\mathbf{p}|^3$ are smaller than the linear-momentum terms in quantum dots by the ratio of z-confinement length to the quantum-dot Bohr radius, and are negligible in the two-dimensional limit (Cerletti, Coish, Gywat and Loss, 2005).

H_{SO} obeys time-reversal symmetry (i.e., H_{SO} is invariant under the operation $\mathbf{p} \to -\mathbf{p}, \boldsymbol{\sigma} \to -\boldsymbol{\sigma}$). Thus, in the absence of a magnetic field, the ground state of a single electron confined to a quantum dot is twofold degenerate due to Kramer's theorem, and H_{SO} alone cannot cause decoherence. The character of the ground-state doublet does change, however, due to the presence of H_{SO}, mixing orbital and spin states. Thus, any fluctuations that couple to the orbital degree of freedom can cause decoherence in combination with spin-orbit coupling. These fluctuations can come from lattice phonons, surrounding gates, electron-hole pair excitations, and so on (Golovach, Khaetskii and Loss, 2004). The longitudinal spin relaxation rate $1/T_1$ due to spin-orbit coupling and lattice phonons has been calculated, and shows a strong suppression for confined electrons (with large level spacing $\hbar\omega_0$) in weak magnetic fields B: $1/T_1 \propto B^5/(\hbar\omega_0)^4$ (Khaetskii and Nazarov, 2000; 2001). This calculation has been extended to a larger range of magnetic fields, showing that the B-field dependence of $1/T_1$ saturates and is then suppressed when the wavelength of the phonons with energy $g\mu_{\mathrm{B}}B$ is comparable to the dot size (Golovach, Khaetskii and Loss, 2004). Further, this calculation has also been extended to include the transverse spin decay time due to spin-orbit interaction alone, showing that dephasing is limited by relaxation, or $T_2 = 2T_1$ to leading order in the spin-orbit coupling, independent of the particular source of fluctuations (Golovach, Khaetskii and Loss, 2004). Additionally, $1/T_1$ has been shown to have a strong dependence on the magnetic field direction, relative to the crystal axes (Fal'ko, Altshuler and Tsyplyatyev, 2005), shows a strong enhancement near avoided level crossings, which may allow independent measurements of the Rashba and Dresselhaus coupling constants (Bulaev and Loss, 2005a), and plays a role in phonon-assisted cotunneling current through quantum dots (Lehmann and Loss, 2006). The relaxation rate of quantum-dot-confined hole spins due to spin-orbit coupling and phonons has also been investigated. In some cases, recent work has shown that the hole spin relaxation time may even exceed the relaxation time of electron spins (Bulaev and Loss, 2005b). In addition to lattice phonons, electric-field fluctuations can result from the noise in a QPC readout device, which results in spin decoherence when considered in combination with spin-orbit coupling. This mechanism shows a strong dependence of the decoherence rate $\left(\sim 1/r^6\right)$ on the dot-QPC separation r (Borhani, Golovach and Loss, 2005), and can therefore be controlled with careful positioning of the readout device.

Measurements of relaxation times for single-electron spins have been performed in gated lateral quantum dots (Hanson *et al*., 2003; Elzerman *et al*., 2004), giving a T_1 time in good agreement with the theory of Golovach, Khaetskii and Loss (2004) and in self-assembled quantum dots (Kroutvar *et al*., 2004), which confirmed the expected magnetic field dependence: $1/T_1 \propto B^5$ (Khaetskii and Nazarov, 2001). Additionally, singlet–triplet decay has been measured in single vertical (Fujisawa *et al*., 2002), and lateral (Hanson *et al*., 2005) dots, as well as lateral double dots (Petta *et al*., 2005b; Johnson *et al*., 2005a).

There is a general consensus that spin relaxation for quantum-dot-confined electrons proceeds through the spin-orbit interaction and phonon emission at high magnetic fields. However, in weak magnetic fields, and for the transverse spin decay time T_2, there are stronger effects in GaAs. These effects are due to the contact hyperfine interaction between confined electron spins and nuclear spins in the surrounding lattice.

5.2 Hyperfine interaction

For a collection of electrons in the presence of nuclear spins, the Fermi contact hyperfine interaction reads

$$H_{\mathrm{hf}} = Av\sum_k \mathbf{I}_k \cdot \mathbf{S}(\mathbf{r}_k),\ \mathbf{S}(\mathbf{r}_k) = \frac{1}{2}\sum_{\sigma,\sigma'=\uparrow,\downarrow} \psi^\dagger_\sigma(\mathbf{r}_k)\boldsymbol{\sigma}_{\sigma\sigma'}\psi_{\sigma'}(\mathbf{r}_k) \tag{26}$$

where A is the hyperfine coupling strength, v is the volume of a crystal unit cell containing one nuclear spin, $\mathbf{I}_k$ is the spin operator for the nuclear spin at site k, $\mathbf{S}(\mathbf{r}_k)$ is the electron spin density at the nuclear site, given

in terms of field operators $\psi_\sigma(\mathbf{r}) = \sum_n \Psi_n(\mathbf{r}) c_{n\sigma}$. Here, $c_{n\sigma}$ annihilates an electron with orbital envelope function $\Psi_n(\mathbf{r})$ and spin σ. The $\Psi_n(\mathbf{r})$ form a complete orthonormal set, from which it follows that $\left\{\psi_\sigma(\mathbf{r}), \psi^\dagger_{\sigma'}(\mathbf{r}')\right\} = \delta(\mathbf{r} - \mathbf{r}')\delta_{\sigma,\sigma'}$, $\left\{\psi_\sigma(\mathbf{r}), \psi_{\sigma'}(\mathbf{r}')\right\} = 0$, and we have denoted matrix elements by $\boldsymbol{\sigma}_{\sigma\sigma'} = \langle\sigma|\boldsymbol{\sigma}|\sigma'\rangle$, where $\boldsymbol{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ is the vector of Pauli matrices. The significance of the general form given in equation (26) is that there can be interplay of orbital and spin degrees of freedom due to the contact hyperfine interaction. When the orbital level spacing is not too large, this interplay can be the limiting cause of electron-spin relaxation (Erlingsson, Nazarov and Fal'ko, 2001; Erlingsson and Nazarov, 2002) in weak magnetic fields, where the spin-orbit interaction is less effective, and leads to enhanced nuclear spin relaxation in the vicinity of sequential-tunneling peaks for a quantum dot connected to leads, where $\mathbf{S}(\mathbf{r})$ fluctuates significantly (Lyanda-Geller, Aleiner and Altshuler, 2002; Hüttel *et al.*, 2004).

The orbital level spacing in lateral quantum dots is usually much larger than the typical energy scale of $H_{\rm hf}$. In this case, it is possible to solve for the ground state orbital envelope wave function $\Psi_0(\mathbf{r})$ in the absence of the hyperfine interaction, and write an effective hyperfine Hamiltonian for a single electron projected onto the quantum-dot orbital ground state:

$$H_{\rm hf,0} \approx \mathbf{h}_0 \cdot \mathbf{S}_0, \;\; \mathbf{h}_0 = Av \sum |\Psi_0(\mathbf{r}_k)|^2 \mathbf{I}_k \qquad (27)$$

where here $\mathbf{S}_0$ is the spin-1/2 operator for a single electron in the quantum-dot orbital ground state. The primary material used to make lateral quantum dots is GaAs. All natural isotopes of Ga and As carry nuclear spin $I = 3/2$. Each isotope has a distinct hyperfine coupling constant, but the average coupling constant, weighted by the relative abundance of each isotope in GaAs gives $A \approx 90\,\mu$eV (Paget, Lampel, Sapoval and Safarov, 1977).

Dynamics under $H_{\rm hf,0}$ have now been studied extensively under many various approximations and in many parameter regimes. Here we give a brief account of some part of this study. For an extensive overview, see reviews in (Schliemann, Khaetskii and Loss, 2003; Cerletti, Coish, Gywat and Loss, 2005). The first analysis of the influence of equation (27) on quantum-dot electron-spin dynamics showed that the long-time longitudinal spin-flip probability, $P_{\uparrow\downarrow} \approx 1/p^2 N$ (Burkard, Loss and DiVincenzo, 1999) was suppressed in the limit of large nuclear spin polarization p and number of nuclear spins in the dot, N. It may be possible to reach high polarizations in a 2DEG by allowing the system to equilibrate at low temperature, below which the nuclei are predicted to undergo a ferromagnetic phase transition (Simon and Loss, 2007). An exact solution for the case of a fully polarized nuclear spin system ($p = 1$) has shown that both the longitudinal and transverse components of the electron spin decay by a fraction $\sim 1/N$ according to a long-time power law $\sim 1/t^{3/2}$ on a timescale of $\tau \sim \hbar N/A$ (Khaetskii, Loss and Glazman, 2002) ($\hbar N/A \sim 1\,\mu$s for a GaAs dot containing $N \simeq 10^5$ nuclei). This exact solution for $p = 1$, which shows a nonexponential decay, demonstrates that the electron spin decay is manifestly non-Markovian since the timescale for motion in the nuclear spin bath is much longer than the decay timescale of the electron spin. For unpolarized systems, the ensemble-averaged mean-field dynamics show a transverse spin decay on a timescale $\tau \sim \hbar\sqrt{N}/A \sim 5\,$ns (Khaetskii, Loss and Glazman, 2002; Merkulov, Efros and Rosen, 2002). The exact solution has been extended to the case of nonzero polarization $p \neq 1$ using a generalized master equation, valid in the limit of large magnetic field or polarization $p \gg 1/\sqrt{N}$ (Coish and Loss, 2004). This work has shown that, while the longitudinal spin decay is bounded by $\sim 1/p^2 N$, due to the quantum nature of the nuclear field, the transverse components of spin will decay to zero in a time $t_c \approx 5\,\text{ns}/\sqrt{1-p^2}$ (without necessarily ensemble averaging and without making a mean-field ansatz), unless an electron spin-echo sequence is performed or the nuclei are prepared in an eigenstate of the operator h_0^z through measurement (Coish and Loss, 2004). There are several recent suggestions for methods that could be used to measure the operator h_0^z (Giedke *et al.*, 2006; Klauser, Coish and Loss, 2006; Stepanenko, Burkard, Giedke and Imamoglu, 2006) in order to extend the electron-spin decay times. Once the nuclear spin system is forced into an eigenstate of h_0^z, the lowest-order corrections for large magnetic field still show incomplete decay for the transverse spin (Coish and Loss, 2004), suggesting that dynamics induced by the nuclear dipolar interaction may limit spin coherence in this regime (de Sousa and Das Sarma, 2003), although higher-order corrections have been reported to lead to complete decay (Deng and Hu, 2006), even when the nuclear spin system is static. There have been several efforts to understand the hyperfine decoherence problem numerically (Schliemann, Khaetskii and Loss, 2002; Shenvi, de Sousa and Whaley, 2005b), and other studies have investigated electron spin-echo envelope decoherence under the hyperfine interaction alone (Coish and Loss, 2004; Shenvi, de Sousa and Whaley, 2005b; Shenvi, de Sousa and Whaley, 2005a) or the combined influence of hyperfine and nuclear dipolar interactions (de Sousa and Das Sarma, 2003; de Sousa, Shenvi and Whaley, 2005; Witzel, de Sousa and Das Sarma, 2005; Yao, Liu and Sham, 2006, 2007). Other approaches to understanding the hyperfine decoherence problem include semiclassical theories that replace the quantum nuclear field by a classical dynamical vector (Erlingsson and Nazarov, 2004; Yuzbashyan, Altshuler, Kuznetsov and Enolskii, 2005) or a classical distribution

function (Al-Hassanieh, Dobrovitski, Dagotto and Harmon, 2006).

Experiments on electron-spin decoherence in single quantum dots (Bracker *et al*., 2005; Dutt *et al*., 2005) and double-quantum dots (Petta *et al*., 2005a; Koppens *et al*., 2005) have now confirmed that the ensemble-averaged electron-spin dephasing time is indeed given by $\tau \sim \hbar\sqrt{N}/A \sim 5\text{–}10\,\text{ns}$.

For two electron spins confined to a double quantum dot, the hyperfine Hamiltonian (equation (26)) can be cast in the form (Coish and Loss, 2005)

$$H_{\text{hf,dd}} = \epsilon_z \sum_l S_l^z + \sum_l \mathbf{h}_l \cdot \mathbf{S}_l$$
$$= \epsilon_z S_l^z + \mathbf{S}\cdot\mathbf{h} + \delta\mathbf{S}\cdot\delta\mathbf{h} \tag{28}$$

$$\mathbf{S}_l = \frac{1}{2} \sum_{\sigma,\sigma'=\uparrow,\downarrow} d_{l\sigma}^{\dagger} \boldsymbol{\sigma}_{\sigma\sigma'} d_{l\sigma'} \tag{29}$$

where $\epsilon_z = g\mu_B B$ is the Zeeman splitting, $d_{1(2)\sigma}$ annihilates an electron in the single-particle orbital state with envelope wave function $\Psi_{1(2)}(\mathbf{r})$ and spin σ, we define $\mathbf{h} = (\mathbf{h}_1 + \mathbf{h}_2)/2$, $\delta\mathbf{h} = (\mathbf{h}_1 + \mathbf{h}_2)/2$, where the quantum nuclear field operators are $\mathbf{h}_{1(2)} = Av \sum_k \left|\Psi_{1(2)}(\mathbf{r}_k)\right|^2 \mathbf{I}_k$, the sum of electron spins is $\mathbf{S} = \mathbf{S}_1 + \mathbf{S}_2$ and the difference is $\delta\mathbf{S} = \mathbf{S_1} - \mathbf{S_2}$. While the sum $\mathbf{S}$ conserves the total squared electron spin, and can only couple states of different z-projection (e.g., $|T_0\rangle$ to $|T_\pm\rangle$), the difference $\delta\mathbf{S}$ does not preserve the total spin, and therefore couples singlet to triplet (e.g., $|S(1,1)\rangle$ to $|T_0\rangle$ and $|T_\pm\rangle$). The difference term $\propto \delta\mathbf{S}$ will therefore lead to anticrossings in the energy level spectrum, where $|S(1,1)\rangle$ and $|T_\pm\rangle$ or $|T_0\rangle$ cross. Adding equation (29) to the previous double-dot Hamiltonian, $H_{\text{dd}} = H_{\text{C}} + H_{\text{T}} + H_{\text{hf,dd}}$, and making a mean-field ansatz for the nuclear field operators, that is, replacing operators by their expectation values: $\mathbf{h} \to \langle\mathbf{h}\rangle$ [3], leads to the energy level spectrum shown in Figure 6. In the limit of large Zeeman splitting ϵ_z and large negative detuning ϵ', an effective two-level Hamiltonian can be derived in the subspace of lowest-energy singlet and $S^z = 0$ triplet ($|S\rangle$, $|T_0\rangle$) (Coish and Loss, 2005):

$$H_{\text{dd,eff}} = \frac{J}{2}\mathbf{S}\cdot\mathbf{S} + \delta h^z \delta S^z + O\left(\frac{1}{\epsilon_z}\right) \tag{30}$$

An exact solution can be found for pseudospin dynamics in the two-dimensional subspace of $|S\rangle$ and $|T_0\rangle$ under the action of $H_{\text{dd,eff}}$. This solution shows that a singlet–triplet correlator undergoes an interesting power-law decay in a characteristic timescale that can be extended by increasing J (Coish and Loss, 2005), and has been verified in experiment (Laird *et al*., 2006). As is true for the transverse components of a single-electron spin, the singlet–triplet correlator shows a rapid decay if the nuclear spin environment is not in an eigenstate of the relevant nuclear field operator (in this case, δh^z). The decay time can be significantly extended by narrowing the distribution in δh^z eigenstates through measurement (Klauser, Coish and Loss, 2006) or by performing a spin-echo sequence (Petta *et al*., 2005a). Remaining sources of dephasing include the corrections to $H_{\text{dd,eff}}$ (of order $1/\epsilon_z$, which cannot be removed easily) and fluctuations in the electrostatic environment, although the effect of these fluctuations can be removed to leading order at zero-derivative points for the exchange interaction (Coish and Loss, 2005), where:

$$\frac{\mathrm{d}J(\epsilon)}{\mathrm{d}\epsilon} = 0 \tag{31}$$

Recent calculations suggest that these zero-derivative points should be achievable with appropriate control of the confinement potential or magnetic field (Hu and Das Sarma, 2006; Stopa and Marcus, 2006).

Since the hyperfine interaction does not preserve the total spin quantum number of electrons, this interaction plays a very important role in studies on spin-dependent transport. In particular, spin blockade (Weinmann, Häusler and Kramer, 1995; Weinmann, 2003) occurs in double quantum dots (Ono, Austing, Tokura and Tarucha, 2002) when tunneling is allowed between spin singlet $|S(1,1)\rangle \to |S(0,2)\rangle$, but not between spin triplets $|T(1,1)\rangle \nrightarrow |T(0,2)\rangle$, because of a large energy cost due to orbital level spacing and the Pauli principle. This blockade allows for the extraction of features at energy scales much less than temperature, making it an ideal parameter regime in which to perform spectroscopy on double dots (Pioro-Ladrière *et al*., 2003) and spin-resonance experiments, which previously suffered from 'heating' effects in single dots (van der Wiel *et al*., 2003; Koppens *et al*., 2006). The hyperfine interaction mixes the $|S(1,1)\rangle$ and $|T(1,1)\rangle$ states, allowing transport, and effectively removing spin blockade when these states are nearly degenerate. This behavior leads to a number of intriguing effects, including stable undriven oscillations in transport current (Ono and Tarucha, 2004; Erlingsson, Jouravlev and Nazarov, 2005), and a striking magnetic field dependence of leakage current, which allows the extraction of information about the nuclear spin system (Koppens *et al*., 2005; Jouravlev and Nazarov, 2006). Even–odd effects in the spin blockade of few-electron quantum dots have further revealed the shell-filling illustrated in Figure 3 (Johnson *et al*., 2005b).

The influence of spin-dependent terms, causing decoherence or unwanted evolution, is a central issue in quantum-dot spin quantum computing. The requirements for fault-tolerant quantum information processing are very stringent. This raises the bar for required understanding of these environmental influences to a very high level, and guarantees that

Table 2. Experimentally determined energy relaxation and decoherence times in single and double quantum dots. (Reproduced by permission of W.A. Coish *et al*., copyright 2006 Wiley VCH.)

	Decay type	Measured decay time (s)
(i)	Energy relaxation time T_1 between Zeeman-split sublevels	$T_1 > 50\,\mu$s (Hanson *et al*., 2003) (lateral GaAs dot), $T_1 = 0.85$ ms at $B = 8$ T (Elzerman *et al*., 2004) (lateral GaAs dot), $T_1 = 20$ ms at $B = 4$ T (Kroutvar *et al*., 2004) (self-assembled Ga(In)As dot), $T_1 = 170$ ms at $B = 1.75$ T (Amasha *et al*., 2006) (lateral GaAs dot).
(ii)	Single-spin coherence time τ_c due to the hyperfine interaction	$\tau_c = 1 - 10$ns (Bracker *et al*., 2005; Braun, *et al*., 2005; Dutt *et al*., 2005).
(iii)	Singlet–triplet energy relaxation time $T_{1,\mathrm{ST}}$	$T_{1,\mathrm{ST}} \simeq 10 - 500\,\mu$s (Fujisawa *et al*., 2002; Sasaki, Fujisawa, Hayashi and Hirayama, 2005) (vertical dot), $T_{1,\mathrm{ST}} \simeq 0.2 - 2.5$ ms (Hanson *et al*., 2005) (lateral dot), $T_{1,\mathrm{ST}} \simeq 1\,\mu\mathrm{s} - 10$ ms (Petta *et al*., 2005b; Johnson *et al*., 2005a) (lateral double dot).
(iv)	Singlet–triplet coherence time due to hyperfine $\tau_{\mathrm{c,ST}}$	$\tau_{\mathrm{c,ST}} \simeq 10$ ns (Petta *et al*., 2005a) (free-induction decay time), $\tau_{\mathrm{c,ST,echo}} \simeq 1.2\,\mu$s (Petta *et al*., 2005a) (spin-echo envelope decay time).
(v)	Orbital inelastic relaxation time $T_{1,\mathrm{orb}}$ for a single-electron charge state in a double quantum dot	$T_{1,\mathrm{orb}} \simeq 16$ ns (Petta *et al*., 2004).
(vi)	Orbital dephasing time τ_ϕ for a single-electron charge state in a double quantum dot	$\tau_\phi \simeq 1$ ns (Hayashi *et al*., 2003), $\tau_\phi \simeq 400$ ps (Petta *et al*., 2004), (see also the comprehensive review in Fujisawa, Hayashi and Sasaki, 2006).

quantum-dot spin decoherence will remain a challenge for some time to come.

5.3 Experimentally measured decay times

To complete this section on decoherence, here we include a table with some of the most relevant measurements of decoherence and energy relaxation times found in single and double quantum dots (see Table 2).

6 ENTANGLEMENT GENERATION, DISTILLATION, AND DETECTION

In addition to the usual requirements for control and coherence, to demonstrate the true quantum nature of qubits, there have been many suggestions to create and measure nonlocal multiparticle entanglement of electron spins in nanostructures (DiVincenzo and Loss, 1999; Burkard, Loss and Sukhorukov, 2000; Loss and Sukhorukov, 2000; Choi, Bruder and Loss, 2000; Egues, Burkard and Loss, 2002; Burkard and Loss, 2003; Samuelsson, Sukhorukov and Büttiker, 2004; Recher, Sukhorukov and Loss, 2001; Lesovik, Martin and Blatter, 2001; Mélin, 2001; Costa and Bose, 2001; Oliver, Yamaguchi and Yamamoto, 2002; Bose and Home, 2002; Recher and Loss, 2002, 2003; Bena, Vishveshwara, Balents and Fisher, 2002; Saraga and Loss, 2003; Bouchiat *et al*., 2003; Beenakker and Schoenenberger, 2003; Saraga, Altshuler, Loss and Westervelt, 2004; Egues *et al*., 2005). These proposals include suggestions to extract a spin singlet from a superconductor through two quantum dots (Recher, Sukhorukov and Loss, 2001) or nanotubes (Recher and Loss, 2002; Bena, Vishveshwara, Balents and Fisher, 2002), or to create entanglement near a magnetic impurity (Costa and Bose, 2001), through a single quantum dot (Oliver, Yamaguchi and Yamamoto, 2002), from biexcitons in double quantum dots (Gywat, Burkard and Loss, 2002), or through a triple dot (Saraga and Loss, 2003). It may also be possible to distill entanglement (Bennett *et al*., 1997) from an unentangled Fermi gas through Coulomb scattering in a 2DEG (Saraga, Altshuler, Loss and Westervelt, 2004).

As well as providing a proof of quantum-mechanical behavior, entanglement can be used as a resource for measurement-based quantum computing. Some measurement-based schemes rely on the creation of highly entangled cluster states (Raussendorf and Briegel, 2001), which could be generated in quantum-dot arrays using the Heisenberg exchange interaction (Borhani and Loss, 2005). Other measurement-based schemes generate entanglement through partial Bell-state (parity) measurements (Beenakker, DiVincenzo, Emary and Kindermann, 2004), which could also be implemented for spins in quantum dots using spin-to-charge conversion (Engel and Loss, 2005; Coish, Golovach, Egues and Loss, 2006). Independent of the method used, the generation or purification and subsequent detection of entangled electron spins would present a significant milestone on the road to a working quantum-dot quantum computer.

7 CONCLUSIONS AND OUTLOOK

We have presented some of the theoretical and experimental challenges to quantum-dot quantum computing with electron spins. The last few years have seen an extremely rapid rate of progress in experiments which show that many of the required elements of a spin-based quantum-dot quantum computer can be realized in principle. The most significant advances include the reduction of the number of electrons confined to gated quantum dots down to a single electron (Ciorga *et al*., 2000), the demonstration (Hanson *et al*., 2003) and improvement (Hanson *et al*., 2005) of electron-spin readout in gated lateral dots, which has led to the measurement of a spin T_1 time (Elzerman *et al*., 2004), the demonstration of the $\sqrt{\text{SWAP}}$ operation, allowing for the extraction of an ensemble-averaged T_2^* time, and spin-echo methods to extend the decay time within a two-spin encoded subspace (Petta *et al*., 2005a), and most recently the demonstration of single-spin rotations under resonant conditions (Koppens *et al*., 2006, 2007).

To demonstrate viability of the Loss–DiVincenzo proposal, more experiments are needed. Although the Loss–DiVincenzo proposal is scalable in principle, it remains to be seen if there are significant practical obstacles to scaling-up the number of electrons involved well beyond two.

NOTES

[1] Optical initialization is likely more practical for the proposal of (Imamoğlu *et al*., 1999), in which the qubit spins can be widely separated and addressed individually or coupled with optical excitation, rather than the Loss–DiVincenzo proposal, where quantum dots are close, in order to maximizing wave function overlap for exchange-mediated qubit coupling.

[2] Note that this type of pulse will generally lead to a smaller value of P for a given set of parameters since here, $\mathrm{d}\epsilon'/\mathrm{d}t \leq \Delta\epsilon/\tau_{\mathrm{sw}}$, whereas for the linear pulse $\mathrm{d}\epsilon'/\mathrm{d}t = \Delta\epsilon/\tau_{\mathrm{sw}}$ for the entire sweep.

[3] In general, great care should be taken in making such a replacement. See the discussion, for example, in (Coish and Loss, 2005) or (Coish, Yuzbashyan, Altshuler and Loss, 2006).

Ohio State University, Columbus, OH, USA

1 INTRODUCTION

The emerging technique of magnetic resonance force microscopy (MRFM) (Sidles, 1991) was conceived by Sidles (1992) as a tool that could provide the revolutionary capability for three-dimensional imaging of single-copy biomolecules. This challenging goal has been augmented by a growing interest in applying it to imaging, especially subsurface imaging, of a broad range of materials and devices including those that are the subject of this handbook.

New materials and devices with unprecedented capabilities and levels of performance are being created by tailoring the structure and composition of multicomponent materials at the nanometer scale. Some of the most important examples are systems incorporating and exploiting electronic spin in its many manifestations including ferromagnetism. A central component of a successful materials development program is the availability of characterization tools. Progress in the development of spin electronics materials and devices will depend on tools capable of providing detailed microscopic information about the electronic, magnetic, and structural properties of these materials systems. In addition to studying the constituents of these systems the ability to image and characterize buried interfaces in multicomponent systems is a particularly important requirement.

The MRFM is a novel scanned-probe instrument which combines the three-dimensional imaging capabilities of magnetic resonance imaging (MRI) with the high sensitivity and resolution of atomic force microscopy. It will enable nondestructive, chemical-specific, high-resolution microscopic studies and imaging of *subsurface* properties of a broad range of materials. Dramatic improvements in the capabilities of the MRFM in the last decade have confirmed the validity of the approach in nuclear magnetic resonance (NMR) (Rugar *et al*., 1994), electron spin resonance (ESR) (Rugar, Yannoni and Sidles, 1992; Hammel, Zhang, Moore and Roukes, 1995; Bruland *et al*., 1998) and ferromagnetic resonance (FMR) experiments (Zhang, Hammel and Wigen, 1996; Wago, Botkin, Yannoni and Rugar, 1998; Zhang *et al*., 1998; Hammel, Zhang and Midzor, 1998). In the quest for improved sensitivity a recent milestone – the detection of a single electronic spin using by MRFM – has been demonstrated by the IBM group (Rugar, Budakian, Mamin and Chui, 2004). Several good reviews are available (Sidles *et al*., 1995; Yannoni, Züger, Rugar and Sidles, 1996; Pelekhov *et al*., 2002; Wigen, Roukes and Hammel, 2006).

Because spatial resolution in MRI is limited by the requirement that adequate signal (compared to detection noise) be obtained from the resolved volume, this breakthrough heralds new horizons in magnetic resonance imaging. This is a unique accomplishment amongst single spin detectors in that MRFM couples directly to the electron's magnetic

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

dipole moment. Other high sensitivity approaches exploit mechanisms that couple the spin of the electron to its spatial degrees of freedom, hence allowing the spin to be detected through its coupling to the electronic charge. The much larger interaction force afforded by coupling to the charge carries the limitations associated with the particular environment required to obtain the needed interaction between the electron spin and orbital degrees of freedom. MRFM is a general technique applicable wherever conventional magnetic resonance would apply, this generality of applicability is a central strength of the MRFM.

The development of MRFM instruments capable of fulfilling these goals will be built on techniques that improve sensitivity and overcome the challenges inevitable in applying them under various the experimental conditions these applications entail. In this chapter, we focus on these two aspects of MRFM: Sections 2–4 discuss the fundamentals of the technique and the various components of a microscope, and in Section 5 several applications to problems will be discussed.

2 UNDERLYING TECHNOLOGIES

2.1 Magnetic resonance

2.1.1 Fundamentals

Electrons and many atomic nuclei possess a magnetic moment μ. This moment is related their spin angular momentum J by the gyromagnetic ratio γ which is unique for each moment

$$\boldsymbol{\mu} = \gamma \mathbf{J} \tag{1}$$

The electronic moment $\mu_e = 9.28 \times 10^{-24}\,\mathrm{J\,T^{-1}} \approx \mu_\mathrm{B}$ is approximately 10^3 times larger than nuclear moments. Because spin moments possess both magnetic moment and angular momentum, the torque exerted by an external magnetic field H results in precession of the moment about the field:

$$\frac{\mathrm{d}\boldsymbol{\mu}}{\mathrm{d}t} = \boldsymbol{\mu} \times \gamma \mathbf{H} \tag{2}$$

The precession frequency (the Larmor frequency) is $\omega_\mathrm{L} = \gamma H$.

A magnetic moment in a magnetic field H exhibits a resonant response to a transverse magnetic field H_1 oscillating at frequency ω_L. This effect emerges in a simple quantum mechanical as well as classical picture. The Hamiltonian for a magnetic moment in a magnetic field H applied along the $\hat{z}$ direction, is

$$\mathcal{H} = -\boldsymbol{\mu} \cdot \mathbf{H} \tag{3}$$

hence,

$$E_m = -\gamma \hbar H m \tag{4}$$

where $m = J, J-1, \ldots, -J+1, -J$ is the projection of the spin angular momentum $\mathbf{J}$ along the field axis $\mathbf{H}$. Therefore the energy of the transition between states having initial and final spin projections m_i and m_f is

$$\Delta E = -\gamma \hbar H \Delta m \tag{5}$$

where $\Delta m = m_f - m_i$. The transition is stimulated by a transverse oscillating field $H_1 = H_1 \hat{x} \cos(\omega t)$. The matrix element for this perturbation is

$$\left\langle m_f \left| -\gamma \hbar H_1 J_x \right| m_i \right\rangle \tag{6}$$

Writing $J_x = (1/2)(J_+ + J_-)$ we see it is nonzero only for $\Delta m = \pm 1$. Thus the energy of the allowed resonant transitions is

$$|\Delta E| = \gamma \hbar H = \hbar \omega_\mathrm{L} \tag{7}$$

and therefore energy is absorbed at the resonant excitation frequency $\omega_\mathrm{L} = \gamma H$.

2.1.2 Spin susceptibility

The spin polarization of an ensemble of N particles of spin J in thermal equilibrium at temperature T with a magnetic field of magnitude H_0 is governed by Boltzmann statistics (Abragam, 1961). The populations of energy levels of the spin system are proportional to $\exp(-E_m/k_\mathrm{B}T)$. The net equilibrium magnetization M of the ensemble is

$$M = N\gamma\hbar \frac{\sum_{m=-J}^{J} m \exp(-E_m/k_\mathrm{B}T)}{\sum_{m=-J}^{J} \exp(-E_m/k_\mathrm{B}T)} \tag{8}$$

Exploiting the high-temperature approximation (usually an excellent approximation) $E_m/k_\mathrm{B}T \ll 1$ we obtain the following expression for M and the spin susceptibility $\chi_0 = M/H_0$:

$$M = \frac{N\gamma^2\hbar^2 J(J+1)}{3k_\mathrm{B}T} H_0 = \chi_0 H_0 \tag{9}$$

2.1.3 Spin relaxation

A spin system that is removed from this thermal equilibrium state will regain it through interactions with its environment, a thermal reservoir, typically the crystal lattice hosting the spin, at temperature T. This process requires transitions between spin states, and these

require fluctuating magnetic fields analogous to the field H_1 described in Section 2.1.1 above. These fields must fluctuate at ω_L and have a component oriented perpendicular to the direction of the polarizing magnetic field H_0. The time evolution of ensemble magnetization M is given by

$$\frac{dM_z}{dt} = -\frac{M_z - M_0}{T_1} \tag{10}$$

where T_1 is the longitudinal spin relaxation time that is determined by the intensity of fluctuations of the transverse local field at the frequency $\omega_L = \gamma H_0$. It describes the process of realigning the spin with the direction of polarizing magnetic field. It can be expressed (Abragam, 1961) in terms of the transverse fluctuating fields $H_\pm$ capable of driving $\Delta m = \pm 1$ transitions between $|m\rangle$ states:

$$\frac{1}{T_1} = \gamma^2 \int_{-\infty}^{\infty} \langle H_\pm(0) H_\pm(\tau)\rangle e^{i\gamma H_0 \tau} d\tau \tag{11}$$

The integral is the spectral density $J_\pm$ of the field fluctuations, given by the Fourier transform of the time autocorrelation function of the field fluctuations, and it describes the intensity of these fluctuations at frequency ω:

$$J_\pm(\omega) = \int_{-\infty}^{\infty} \langle H_\pm(0) H_\pm(\tau)\rangle e^{i\omega\tau} d\tau \tag{12}$$

Hence we see that the rate at which spins relax is proportional to this spectral density evaluated at the Larmor frequency, that is, those fluctuating fields capable of causing $\Delta m = \pm 1$ transitions.

A monochromatic transverse field H_1 can coherently rotate M_z into the $\hat{x}-\hat{y}$ plane thus generating a transverse magnetization M_x and M_y; this magnetization will subsequently decay for two reasons. Inhomogeneous relaxation results if different spins experience different magnetizing fields due to spatial inhomogeneity. Different spins will precess at different frequencies causing loss of coherence and eventually loss of the transverse magnetization. A Lorentzian distribution of fields with a half-width ΔH will decohere the transverse magnetization on a timescale:

$$T_2^* = (\gamma \Delta H)^{-1} \tag{13}$$

Interactions between nuclear spins also cause decoherence of the transverse magnetization; these are described by transverse spin relaxation time T_2: (Abragam, 1961)

$$\frac{dM_x}{dt} = -\frac{M_x}{T_2}, \frac{dM_y}{dt} = -\frac{M_y}{T_2} \tag{14}$$

2.1.4 Rotating frame of reference

It is helpful in understanding the dynamics of spins simultaneously experiencing static and oscillating transverse fields to apply a simple transformation (Slichter, 1989) into a frame of reference that rotates about the axis defined by the applied field $\mathbf{H}_0$ (typically $\hat{z}$). The linearly polarized transverse oscillating rf field $H_x = 2H_1 \cos(\omega_{rf} t)$ that is applied in magnetic resonance can be written as a superposition of two oppositely circularly polarized fields of amplitude H_1 rotating with frequencies $\pm\omega_{rf}$ (Abragam, 1961). In practice, only one of the circularly polarized components need be considered since the counter-rotating component is far off resonance ($2\omega_{rf}$) and has little effect on the spin system. In a frame rotating at ω_{rf} the first oscillating field is static, so the magnetic field seen by a spin (see Figure 1) is given by:

$$\mathbf{H}_{eff} = \left(H_z^{tot} - \frac{\omega_{rf}}{\gamma}\right)\hat{z} + H_1\hat{x} \tag{15}$$

Here $H_z^{tot} = H_0 + H_z^{tip}$ to explicitly allow for the fact that in MRFM the field of the micromagnetic tip H_{tip} adds to the field experienced by the sample. In the rotating frame, the resonance condition leads to a particularly simple situation:

$$\frac{\Delta\omega}{\gamma} = H_z^{tot} - \frac{\omega_{rf}}{\gamma} = 0 \Rightarrow \mathbf{H}_{eff} = H_1\hat{x} \tag{16}$$

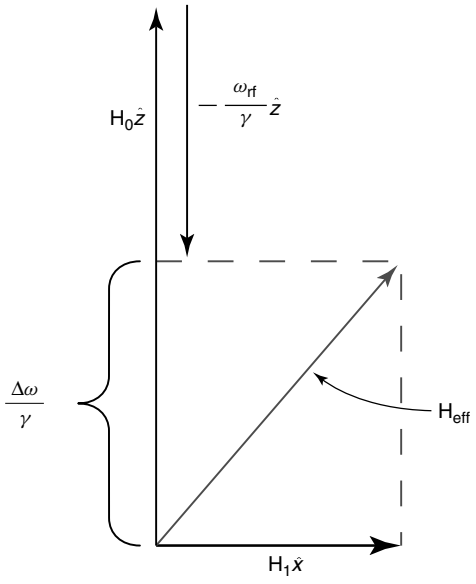

Figure 1. Diagram of magnetic fields in a frame of reference rotating about $\hat{\mathbf{z}}$ with angular frequency ω_{rf}. The resulting effective field $\mathbf{H}_{eff}$ is the vector sum of the applied magnetic field $\mathbf{H}_0$, the transverse field $\mathbf{H}_1$ and the field $-(\omega_{rf}/\gamma)\hat{z}$ that accounts for the transformation to the rotating frame of reference.

Hence the magnetization precesses about $H_1\hat{x}$ at a frequency γH_1, the Rabi frequency. The $\hat{x}$ component of H^{tip} is static and much less than H_0, so it can be neglected.

2.1.5 The Bloch equations

The equations of motion (equation (2)) for the magnetization **M** can be written in the rotating frame of reference including longitudinal and transverse spin relaxation as

$$\frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} = \gamma\,(\mathbf{M} \times \mathbf{H}_{\text{eff}}) - \frac{M_x\hat{x} + M_y\hat{y}}{T_2} - \frac{M_z - M_0}{T_1}\hat{z} \quad (17)$$

The steady-state solutions of these, the well-known Bloch equations (Bloch, 1946; Abragam, 1961), are

$$M_x = \frac{\Delta\omega\gamma H_1 T_2^2}{1 + (T_2\Delta\omega)^2 + \gamma^2 H_1^2 T_1 T_2} M_0 \quad (18)$$

$$M_y = \frac{\gamma H_1 T_2}{1 + (T_2\Delta\omega)^2 + \gamma^2 H_1^2 T_1 T_2} M_0 \quad (19)$$

$$M_z = \frac{1 + (\Delta\omega T_2)^2}{1 + (T_2\Delta\omega)^2 + \gamma^2 H_1^2 T_1 T_2} M_0 \quad (20)$$

where $\Delta\omega = \omega_{\text{rf}} - \omega_{\text{L}}$. The frequency dependence of $M_z(\omega)$, related to the magnetic resonance lineshape, is a (negative-going) Lorentzian whose minimum occurs at $\Delta\omega = 0$. The linewidth, or full width at half intensity, $\delta\omega$ is

$$\delta\omega = 2\frac{\sqrt{1 + \gamma^2 H_1^2 T_1 T_2}}{T_2} \quad (21)$$

2.2 Magnetic resonance imaging

Magnetic resonance imaging (MRI) is a large and rich field that employs an applied magnetic field gradient to map the spatial location of a particular volume onto either the frequency or the applied homogeneous field of a detected magnetic resonance signal. The relationship between the frequency ω_{L} of a spin and the magnetic field H it experiences is

$$\omega_{\text{L}} = \gamma H \quad (22)$$

A magnetic field gradient applied along the $\hat{z}$ direction $\mathrm{d}H/\mathrm{d}z$ creates a spatial distribution of spin resonant frequencies:

$$\omega_{\text{L}}(z) = \gamma\left(H_0 + \frac{\mathrm{d}H_z}{\mathrm{d}z}z\right) \quad (23)$$

Conventional MRI (Callaghan, 1991) employs pulsed magnetic resonance techniques that produce a time-domain spin echo signal. This signal will decay rapidly as a consequence of the broad range of fields present, that is, it will exhibit a short T_2^* (see equation (13)). The Fourier transform of this time-domain decay will produce spectrum in which the signal intensity at a particular frequency corresponds to the number spins at the z-coordinate prescribed by the field gradient.

Alternatively, one can employ monochromatic rf radiation of frequency ω_{rf}, then only those spins lying on a surface of constant field (perpendicular to the field gradient) at z_{res} will contribute to the signal:

$$z_{\text{res}} = \frac{\left(\frac{\omega_{\text{rf}}}{\gamma} - H_0\right)}{\frac{\mathrm{d}H_z}{\mathrm{d}z}} \quad (24)$$

The thickness δz of the resonance volume is determined by the *homogeneous* linewidth of the sample $(\gamma T_2)^{-1}$

$$\delta z = \frac{(\gamma T_2)^{-1}}{\frac{\mathrm{d}H_z}{\mathrm{d}z}} \quad (25)$$

This width determines the spatial resolution of MRI.

The resolution of MRI is limited by detection sensitivity and the requirement that the resolved volume be large enough to provide acceptable signal-to-noise ratio. Pulsed MRI protocols employ pulsed spatial field gradients applied along three orthogonal directions combined with rf pulses to assign a unique value of spin precession frequency and phase to spins within a resolved region having volume $(\delta z)^3$. We see from equation (25) that spatial resolution can be improved by increasing the field gradient strengths. This improvement comes at the price of diminished signal which is proportional to the number of spins $N_{\text{spins}} = n(\delta z)^3$ in the volume element (n is the spin density). Conventional spectrometers can detect the signal from 10^9 electron spins ($\sim 10^{15}$ nuclear spins) in bandwidths of order 1 Hz. The finest spatial resolution reported in inductively detected nuclear micro-MRI is at the level of $(\sim 3\,\mu\text{m})^3$ (Ciobanu, Seeber and Pennington, 2002).

2.3 Scanned-probe microscopy

Scanned-probe microscopy (SPM) refers to a large family of experimental techniques based on detection of a local interaction between a sample and a microscale probe that can be precisely positioned over the sample. Raster scanning of the microprobe over the sample surface provides a spatial map of the detected interaction.

2.3.1 Scanning tunneling microscopy

The first scanned-probe microscope was the scanning tunneling microscope (STM) invented by Gerd Binnig and Heini Rohrer in 1982. In this instrument an atomically sharp

conducting needle is brought close to conducting surface, close enough for electrons tunnel through the vacuum gap (typically $\sim$1 Å) between the tip and the surface in the presence of a potential difference. The extremely short range of the tunneling interaction allows mapping of the local density of electronic states with atomic scale resolution. Mapping of surface topography, local state spectroscopy, and atomic manipulation have all been accomplished with the STM. The STM is, however, limited to conducting surfaces.

2.3.2 Atomic force microscopy

The atomic force microscope (AFM) uses as a probe a flexible micromechanical cantilever with a sharp tip. The interaction between this probe and the surface is detected by measuring the resulting displacement of the cantilever. The typical magnitude of the forces involved is 10^{-9}–10^{-12} N. The displacement of the cantilever is measured using optical displacement detection. The AFM can operate on insulating as well as conducting surfaces, and also provides information about the surface of the sample. AFM can be used for mapping surface topography, stiffness, local friction, and for surface manipulation. It is usually operated in one of two modes: contact mode and noncontact mode. In contact mode the cantilever is in hard contact with the surface and the displacement of the cantilever under the influence of the force of Pauli repulsion is measured. In noncontact mode, an oscillating cantilever hovers above the sample surface and the local gradient of the long-range dipolar (Van der Waals) force is measured by detecting the consequent shift of the natural frequency of the cantilever ω_c. The spatial resolution of AFM is defined, depending on the mode of operation, by parameters such as the radius of the cantilever tip (typically $\sim$10 nm) and the probe–sample separation. Under proper conditions atomic resolution is achievable (Giessibl, 2003).

2.3.3 Magnetic force microscope

The magnetic force microscope (MFM) is a form of AFM that detects the dipolar magnetostatic interaction between the magnetic tip and magnetic dipoles in a ferromagnetic sample. The tip is scanned at a controlled distance above the sample without direct contact. The typical probe–sample interaction has similar magnitude: 10^{-9}–10^{-12} N.

3 THE MRFM INSTRUMENT

MRFM is similar to MFM; the essential difference is the addition of an applied rf field to enable the sample magnetization to be manipulated by magnetic resonance techniques. Because the goal is high spatial resolution imaging, the signal detected is, in general, from a small number of paramagnetic spins, hence the forces are much smaller than in the case of other force microscopies.

A micromechanical cantilever with a micromagnetic probe tip is brought close to the sample surface. The force F exerted on the magnetic tip by magnetic moments in the sample is

$$\mathbf{F} = -(\mathbf{m} \cdot \nabla)\mathbf{B} \tag{26}$$

where $\mathbf{m}$ is the magnetic moment of the sample and $\nabla\mathbf{B}$ is the gradient of the magnetic field of the micromagnetic tip. This force will deflect the compliant cantilever; sensitive displacement detection allows this force to be measured. Using magnetic resonance techniques, the sample magnetization is manipulated at or near the resonant frequency ω_c of the cantilever. The amplitude of the cantilever response is multiplied by Q thus reducing the demands on the displacement detection. Forces as small as 10^{-18} N have been detected (Hoen *et al*., 1994). MRFM can be applied for detection of any kind of magnetic resonance: ESR, NMR, and FMR. Force detection of magnetic resonance detection is far more sensitive than conventional inductive detection, and recently Rugar and coworkers demonstrated MRFM detection of a single electron spin (Rugar, Budakian, Mamin and Chui, 2004). By comparison, the sensitivity of a commercially available inductively detected ESR spectrometer is $\sim 10^9$ spins.

3.1 Micromechanical resonator

The heart of the MRFM is the resonant micromechanical force sensor. The most commonly used structure is a micromechanical beam of length L, width W and thickness T typically clamped at one end, that is, configured as a cantilever, though doubly clamped is also feasible. Other structures such as torsional oscillators (Barrett *et al*., 1998) have also been used for MRFM force detection however, cantilevers are by far more popular and we will focus on them here. MRFM cantilevers with characteristic dimensions $L \approx 300$–$500\,\mu$m, $W \approx 20\,\mu$m and $T \approx 0.5\,\mu$m (see Figure 2) can be fabricated by standard surface micromachining techniques (Madou, 2002). Most commonly MRFM cantilevers are made from Si and Si_3N_4.

3.1.1 The cantilever as a simple harmonic oscillator

The motion of a micromechanical beam resonator is described by the Euler- Bernoulli equation

$$\frac{\partial^2}{\partial x^2}\left[EI(x)\frac{\partial^2}{\partial x^2}z(x,t)\right] + \rho A(x)\frac{\partial^2}{\partial t^2}z(x,t) = F(x,t) \tag{27}$$

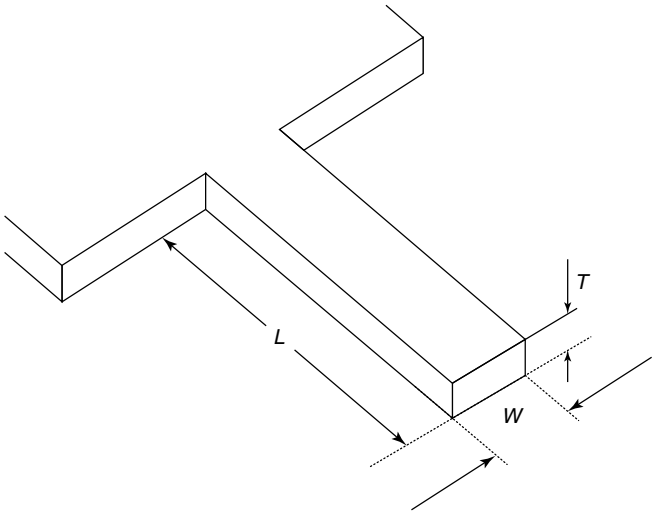

Figure 2. Schematic diagram of simple rectangular micromechanical cantilever.

where $z(x,t)$ is the transverse displacement of the beam, x is the coordinate along the beam, t is time, E is Young's modulus, ρ is the mass density, $I(x)$ is the moment of inertia about the centroid of the beam, $A(x)$ is the cross-sectional area of the beam and $F(x,t)$ is the external applied force. It can be shown that small vibrations at a coordinate x on the beam can be described by a point mass-on-spring model with effective parameters obtained from equation (27) using appropriate boundary conditions. The resulting equation of motion, with dissipation terms included, is that of a simple harmonic oscillator (SHO):

$$m\frac{\partial^2}{\partial t^2}z(t) + \frac{m\omega_c}{Q}\frac{\partial}{\partial t}z(t) + kz(t) = F(t) \tag{28}$$

where the effective parameters are the resonant frequency of the cantilever ω_c, the effective mass m of the resonator, the quality factor Q and the spring constant k of the resonator.

3.1.2 Resonator parameters

The effective parameters in equation (28) for the fundamental vibration mode are obtained from equation (27)

$$\omega_0 = a_1\sqrt{\frac{ET^2}{\rho L^4}} \tag{29}$$

$$k = a_2\frac{ET^3W}{L^3} \tag{30}$$

$$m = a_3\rho LTW \tag{31}$$

The numerical prefactors depend on x and the boundary conditions used to solve equation (27). If x corresponds to the free end of a simple rectangular cantilever (shown in Figure 2), the prefactors are $a_1 \approx 1.0$, $a_2 \approx 0.25$ and $a_3 \approx 0.25$.

3.1.3 Resonator response to oscillatory excitation

MRFM force detection exploits the response of a cantilever to an oscillatory force

$$F(t) = F_0 e^{\iota\omega t} \tag{32}$$

In the low damping approximation ($Q \gg 1$) the cantilever displacement is

$$z(\omega,t) = A_0 e^{\iota(\omega t+\theta_0)} + e^{-\frac{\omega_c}{2Q}t}\left(C_1 e^{-\iota\omega_c t} + C_2 e^{\iota\omega_c t}\right) \tag{33}$$

where

$$A_0(\omega) = \frac{F_0/m}{\sqrt{(\omega_c^2-\omega^2)^2 + (\omega_c\omega/Q)^2}} \tag{34}$$

$$\theta_0(\omega) = \arctan\left[\frac{\omega_c\omega}{Q(\omega^2-\omega_c^2)}\right] \tag{35}$$

where C_1 and C_2 are complex coefficients determined by initial conditions.

The first term of equation (33) gives the steady-state response of the cantilever. While the response of the cantilever to a static force F_0 is $A_0(0) = F_0/k$ the response to an oscillatory force of the same magnitude at $\omega = \omega_c$ is $A_0(\omega_c) = QF_0/k$, that is the oscillation amplitude is multiplied by the quality factor Q of the cantilever, typically 10^4–10^5, compared to the off-resonant response. This has the important consequence of reducing the *displacement readout* sensitivity (see Section 3.2) needed to ensure that it doesn't limit overall sensitivity.

The second term in equation (33) represents the transient response of the cantilever which decays on the oscillator response timescale

$$\tau = \frac{2Q}{\omega_c} \tag{36}$$

This reflects the fact that changing the amplitude involves changing the oscillator energy by means of the rather small signal force. When an oscillatory force is applied to an otherwise undriven resonator its oscillation amplitude will grow until a steady state is reached in which the work done by the external force (on resonance the force is in phase with the velocity, so it performs work) is balanced by the energy dissipated per cycle ($\propto Q^{-1}$). The response time τ reflects the time required to increase the energy of the resonator to this equilibrium. This time can be long for the high Q cantilevers used in MRFM: typically $Q \sim 5\times10^4$ and $\omega_0 = 2\pi\times10^4$ Hz, so $\tau \approx 1.6$ s. This slow response

can be substantially improved by the application of negative force feedback without significantly degrading the cantilever force sensitivity (Mertz, Marti and Mlynek, 1993; Bruland, Garbini, Dougherty and Sidles, 1996) if necessary.

3.2 Displacement detection

3.2.1 Optical interferometry

Optical displacement detection based on fiber-optic interferometry (Albrecht, Grütter, Rugar and Smith, 1992) is currently nearly universal in MRFM experiments. Laser light launched into one port of a directional fiber coupler (see Figure 3) propagates to the end of the fiber positioned a distance δ from the backside of the cantilever. The gap between the end of the fiber and the reflective cantilever surface forms an interferometric cavity. Cantilever motion changes this gap altering the interference between the reference beam internally reflected off the end of the fiber and the signal beam reflected off the cantilever and back into the fiber. The dependence of the light power on δ is

$$P_p \propto P_{s0} + P_{r0} + 2\sqrt{P_{s0}P_{r0}}\cos\left(\frac{4\pi}{\lambda}\delta\right) \tag{37}$$

where λ is the wavelength of the laser light and P_{s0} and P_{r0} are the powers of the signal and reference beams respectively. To maximize the displacement sensitivity $\mathrm{d}P_p/\mathrm{d}\delta$, the interferometric cavity should be tuned such that

$$\delta = \frac{\lambda}{4}\left(\frac{1}{2} \pm n\right), \quad n = 1, 2, 3 \ldots \tag{38}$$

The amplitude of the reference and the signal beams depends on the power of the laser light P_{laser} and on the reflectivity R_s of the cantilever and R_r of the end of the fiber, so the displacement sensitivity is

$$\left|\frac{\mathrm{d}P_p}{\mathrm{d}\delta}\right| = \frac{8\pi}{\lambda}P_{\mathrm{laser}}(1 - R_r)R_sR_r \tag{39}$$

The sensitivity can be optimized by tuning the reflectivity of the interferometric surfaces with a metallic coating. A displacement noise floor of $10^{-13}\,\mathrm{m\,Hz^{-1/2}}$ can be straightforwardly achieved.

3.2.2 Alternative displacement detection methods

While optical fiber interferometric displacement detection is quite popular, there are other approaches that offer advantages, for instance, in applications to photosensitive samples or where straightforward electrical readout is desired, perhaps at the expense of displacement sensitivity.

Piezoresistive

Piezoresistive displacement detection is based on measuring the change in resistance of the cantilever material resulting from stress induced by cantilever displacement. This approach has been implemented (Arlett *et al.*, 2006) with good sensitivity in Si cantilevers supported by two thin legs with a thin piezoresistive (p^+ Si) top layer. The p^+ layer forms a continuous current path through the legs, and bending will induce a stress σ leading to a change ΔR in the resistance of this path. This can in turn be related to displacement Δz of the end of the cantilever:

$$D \equiv \frac{\Delta R}{R}\frac{1}{\Delta z} = \frac{\Pi_{\mathrm{eff}}\sigma}{\Delta z} = \Pi_{\mathrm{eff}}\frac{3}{2}E\frac{h}{L^2}\left(1 - \frac{\lambda}{2L}\right) \tag{40}$$

where Π_{eff} is the effective piezoresistive coefficient of the material, E is Young's modulus, L is the length of the cantilever, h is its thickness and λ is the length of the piezoresistive region.

The minimum detectable displacement δz_{min} of the cantilever, limited by the Johnson noise in the resistor and $1/f$ noise (Yu *et al.*, 2001), is

$$\delta z_{\mathrm{min}} = \frac{4}{DV}\left[\frac{\alpha V^2}{N}\ln\frac{f_1}{f_2} + 4k_{\mathrm{B}}TR(f_1 - f_2)\right]^{1/2} \tag{41}$$

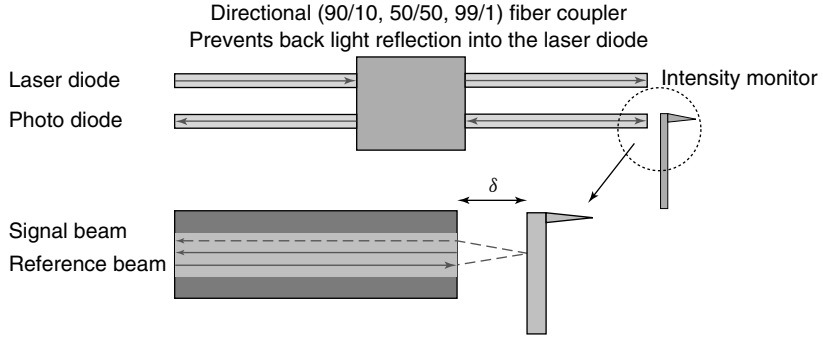

Figure 3. Schematic diagram of the optical fiber interferometer. δ is the distance between the end of the fiber and the cantilever.

where V is the bias voltage, α the $1/f$ noise parameter, N the number of carriers and f_1 and f_2 the upper and the lower limits of the measurement bandwidth. The typical displacement noise floor reported with piezoresistive cantilevers is of the order of $10^{-11}\,\mathrm{m\,Hz^{-1/2}}$ at room temperature. Experimental force sensitivities of $235\,\mathrm{aN\,Hz^{-1/2}}$ and $17\,\mathrm{aN\,Hz^{-1/2}}$ have been obtained at room temperature and 4.2 K, respectively (Arlett *et al*., 2006); optimal performance was obtained at an excitation current that balanced the opposing influences of readout noise and self heating.

Though this detection scheme has yet to be used in MRFM experiments, an integrated piezoresistive displacement detector offers the advantage that there is no need for precision alignment of the cantilever with the detector. This step can be time consuming and its elimination could simplify MRFM experiments and hasten the dissemination of MRFM techniques to a broad research community.

Capacitive displacement detection using a microwave tank circuit

The capacitance between two electrodes varies with separation, so the displacement of a cantilever can be detected by measuring the capacitance C_p between the micromechanical resonator and a sensing electrode. Assuming small cantilever displacements, the corresponding change of the capacitance δC_p is

$$|\delta C_p| = C_p \frac{\delta d}{d} = \epsilon\epsilon_0 \frac{A}{d}\frac{\delta d}{d} \tag{42}$$

where A is the area of capacitor plates, d the distance between the plates and δd is the displacement of the resonator.

When added in parallel to the capacitance of a microwave tank circuit, C_p will lead to a measurable shift in its resonance frequency ω_{res}. The analysis of the noise performance of a tank circuit is identical to that of an SHO. The minimum detectable displacement (Pelekhov *et al*., 2005) depends on temperature T and the quality factor Q of the tank circuit. Capacitive displacement detection promises extremely high displacement detection sensitivity. For typical cantilever parameters we can expect a displacement noise floor of $10^{-13}\,\mathrm{m\,Hz^{-1/2}}$ at room temperature. Because the signal depends on the area of the electrode on the cantilever, this approach does not scale well as cantilevers become smaller.

This method has been used for MRFM signal detection (Pelekhov *et al*., 2005) but self heating of the tank circuit by the drive was evident at low temperatures. The tradeoff between displacement sensitivity and self heating can be helped by lithographic integration of the detection circuit with the cantilever.

Capacitive displacement detection using a single electron transistor

Another approach to capacitive displacement detection (LaHaye, Buu, Camarota and Schwab, 2004) exploits the excellent charge sensitivity of the radio frequency single electron transistor (rf SET) (Devoret and Schoelkopf, 2000). The SET is a superconducting island coupled to drain and source contacts through two tunnel junctions. The conductivity and hence the impedance of the SET arises from the tunneling of individual electrons through the tunnel contacts, and is very sensitive to the alignment of the chemical potential of the drain and source contacts. Slight changes of the island potential are evident in the SET conductance. A microwave tank circuit is used to match a room temperature detector to the impedance of the SET. On resonance, the impedance of the tank circuit is small and therefore the reflectance of the circuit is determined by the differential resistance R_d of the SET. This enables continuous, sensitive readout of the SET impedance.

When the cantilever is voltage biased and capacitively coupled to the SET, its displacement will modify R_d and hence the reflected rf power. At the low temperatures (below 300 mK) where the SET is typically operated its displacement noise is dominated by the tunnel current shot noise and the back action noise of the SET on the cantilever (LaHaye, Buu, Camarota and Schwab, 2004; Zhang and Blencowe, 2001). Theoretical estimates predict a displacement noise floor as low as $10^{-16}\,\mathrm{m\,Hz^{-1/2}}$; in the lab $3.8 \times 10^{-15}\,\mathrm{m\,Hz^{-1/2}}$ has been demonstrated using a 20 MHz beam resonator (LaHaye, Buu, Camarota and Schwab, 2004). Although it requires ultralow temperatures and has only been applied to doubly clamped beams to date, SET displacement detection is currently the most sensitive available.

3.3 Radio frequency magnetic fields

A fundamental requirement for MRFM is the transverse rf magnetic field used to manipulate the sample magnetization. The quality of the resulting force signal depends sensitively on the strength of the transverse oscillatory magnetic field H_1 that manipulates the magnetization. Standard rf field generation techniques are difficult to apply for MRFM because its scanning probe microscope arrangement makes placement of the sample and the MRFM probe inside of an rf coil (NMR) or a microwave cavity (ESR, FMR) virtually impossible. Instead, the sample must be placed as close as possible to the microstrip resonator or a microcoil used to generate the field which must be impedance matched to the 50 Ω source impedance of the rf/microwave signal generator. The nature of the impedance matching network depends on the frequency.

In the rf regime (∼100 MHz) a standard NMR tank circuit using lumped capacitive elements works well (see, e.g., Fukushima and Roeder, 1981). The microwave field needed for ESR or FMR experiments is somewhat more involved since lumped capacitive elements become impractical at these frequencies (3–10 GHz). Design strategies based on distributed microwave structures constructed from microstriplines (50 Ω planar transmission geometry with a signal line separated from a planar ground plane by a dielectric sheet) are useful. Resonant structures are desirable to increase the field; these can be based on either resonant microstriplines or microcoils.

3.3.1 Microstrip resonator

A microstrip resonator (Wallace and Silsbee, 1991) is a section of a microstrip line whose length is half the wavelength λ of the electromagnetic wave at the desired frequency $\omega_{\rm rf}$. The rf power is delivered by a transmission line that is capacitively or inductively coupled to the conducting island. The planar nature of microstrip resonators is convenient for use in scanned-probe experiments as the sample can be placed directly on the resonator (Zhang *et al.*, 1998).

3.3.2 Microcoil

A conventional coil provides a somewhat larger H_1 since the field is a sum of contributions from several windings of the coil. The need to generate rf field in GHz regime limits the inductance of the coil and therefore its size and the number of windings. The coil can be matched to the rf source by a distributed impedance matching network (Wallace and Silsbee, 1991; Zhang *et al.*, 1998; Mamin, Budakian and Rugar, 2003). Typically, ∼250 μm diameter coils with 2–2.5 windings are used. The sample is placed outside the coil on its main axis within one coil radius of the coil to achieve reasonable H_1 intensity so alignment is more demanding than for a microstrip resonator. A normal metal coil implementation delivers 1–3 G (up to ∼9 GHz) with about 10 mW of rf power delivered to the circuit.

Superconducting circuits provide strong H_1 at low power input (Mamin, Budakian and Rugar, 2003). Using this approach, a 7 G microwave field has been demonstrated ∼100 μm from a 220 μm diameter coil with 2.5 windings using only 400 μW of applied power (Mamin, Budakian and Rugar, 2003). Low applied power is important in a cryogenic environment where the heat load must be minimized. There is, however, a significant limitation imposed by superconducting resonators: the applied static field must be well below the superconducting critical field of Nb which limits the applied field to ≈2000 G. This is sufficient for ESR experiments but limiting for NMR detection.

3.4 Micromagnetic probe tips

One of the most powerful means of increasing the tip-sample interaction (equation (45)) and hence MRFM sensitivity is to increase the magnetic field gradient of the probe tip. The component of the field gradient that generates the needed force perpendicular to the plane of the cantilever will depend on the orientation of the cantilever relative to the sample surface and on the polarization of magnetic moments in the sample. For a typical geometry (as in Figure 6) we seek to maximize $\mathrm{d}B_z/\mathrm{d}z$. In a $\sim 10^5\,\mathrm{T\,m^{-1}}$ field gradient, a single electron spin generates a force of 10^{-18} N; much higher gradients will be needed for single nuclear spin sensitivity. This will require close approach to a micromagnetic probe tip.

Although not necessarily the optimal shape, we can consider a spherical ferromagnetic micromagnet to illustrate the challenge. A sphere of radius a uniformly magnetized along $\hat{z}$ with saturation magnetization M_s will have total moment $m_0 = (4/3)\pi a^3 M_s$ (see Figure 6). The field gradient a distance z from the center of the sphere is given by

$$\frac{\mathrm{d}B_z}{\mathrm{d}z} = -6\frac{\mu_0}{4\pi}\frac{m_0}{z^4} \tag{43}$$

Here $z = a + d$, where d is the gap between the sample an the magnetic sphere. For a given operating distance d, the maximum field gradient of a spherical probe magnet is achieved for a radius $a = 3d$. Given state-of-art force detection sensitivity (Rugar, Budakian, Mamin and Chui, 2004) gradients of 10^7–$10^8\,\mathrm{T\,m^{-1}}$ will be needed for single nuclear spin detection. To obtain this from an ($\mu_0 M_s = 2.2$ T) nanosphere will require $d = 46$ nm and $a = 138$ nm ($10^7\,\mathrm{T\,m^{-1}}$) or $d = 4.6$ nm and $a = 14$ nm ($10^8\,\mathrm{T\,m^{-1}}$).

The selection of the magnetic tip goes beyond the size of magnetic particle. Depending on the goals of the experiment, which might not necessarily be a single nuclear spin detection, magnetic coercivity, material stability, ease of fabrication, and the response of the magnetic tip to applied magnetic and rf fields should be considered.

3.4.1 Tip materials

Magnetic materials available for MRFM tip fabrication can be divided into magnetically 'soft' and 'hard' magnetic materials according to their coercivity.

Typically transition metals such as Co, Fe, and Ni have low coercivity, but high saturation magnetization. Fabrication is straightforward and compatible with typical microlithographic processes. This makes soft magnets attractive fabricating magnetic tips.

Hard magnetic materials such as the rare-earth alloys $SmCo_5$, Sm_2Co_{17} and $Nd_2Fe_{14}B$ exhibit coercive fields as

high as 2–3 T. Magnetic tips fabricated out of hard magnetic materials have the advantage that they can be used in MRFM experiments where an externally applied field B_{ext} antiparallel to the orientation of the tip magnetization is desired; there are applications for which this is valuable (see Section 5).

High coercivity offers another advantage. When mounted on an oscillating cantilever in an applied magnetic field, soft magnets are dissipative (Stipe *et al*., 2001a) due to magnetic 'friction' occurring as the particle's moment rotates while trying to follow the direction of the external magnetic field. This dissipation reduces the quality factor Q of the cantilever thus reducing MRFM sensitivity.

We will see in Section 5.2.1 that a long spin lifetime is crucial for ultrasensitive MRFM detection as the noise bandwidth is set by the inverse of this lifetime. Magnetic field fluctuations arising from thermal fluctuations of the tip moment will contribute to spin relaxation in the sample (see Section 2.1.3). Magnetic materials with large magnetic anisotropy K (typically larger in hard magnetic materials) reduce this effect.

3.4.2 Tip fabrication

High coercivity tips are important for high sensitivity MRFM to minimize relaxation due to tip moment fluctuations. Micromagnetic rare-earth tips are fabricated by a two step process: first small particles of the tip material are glued to the cantilever in the presence of an applied magnetic field to orient the tip moment in the desired direction. The tip is then shaped using focused ion beam milling (FIB). This technique can generate tips with gradients exceeding $10^5\,\text{T}\,\text{m}^{-1}$ ($1\,\text{G}\,\text{nm}^{-1}$). An example is shown in Figure 4.

3.4.3 Tip characterization

Characterizing the magnetic moment and the field gradient of the micromagnetic probe tip is essential and challenging due to the very small magnitude the probe magnetic moment and the need to accurately map the spatial variation of the tip field on the scale of tens or hundreds of nanometers.

Vibrating cantilever magnetometry (Zhang and Hammel, 1999; Chabot and Moreland, 2003; Stipe *et al*., 2001b) is a convenient method uniquely capable of measuring the magnetic moment of a small ferromagnetic particle mounted on a micromechanical cantilever. This approach is sensitive to moments as small as $10^4\mu_{\text{B}}$ (Stipe *et al*., 2001b) and so is suitable for the study of nanoscale magnetic tips. The motion of a magnetic particle at the end of a cantilever entails rotation its magnetic moment with respect to the externally applied magnetic field; this leads to a restoring torque that depends on the position of the cantilever and so changes the effective cantilever spring constant. The cantilever is driven at constant amplitude its natural frequency ω_c by means of positive feedback, and the change of its frequency is measured as a function of external magnetic field. The resulting frequency shift $\Delta\omega$ (Stipe *et al*., 2001b) is

$$\Delta\omega = \omega_c \frac{m H H_k}{2kL_e^2(H + H_{\text{K}})} \tag{44}$$

where m is the magnetic moment of the particle, L_e is the effective length of the cantilever, H_k is the anisotropy field of the tip and H is the applied magnetic field. Typical cantilever magnetometry data is shown in Figure 5. The magnetic moment of the magnetic tip can be extracted from the slope of the field dependence. Parameters such as coercivity can also be extracted. Reversals of the magnetization in response to field reversal in a soft magnet are clearly evident as slope changes.

4 FORCE DETECTION OF MAGNETIC RESONANCE

At the heart of MRFM is sensitive detection of the force $\mathbf{F}$ between a magnetic tip generating a field gradient $\nabla\mathbf{B}$ and the magnetization $\mathbf{m}$ in a localized region of the sample

$$\mathbf{F} = -(\mathbf{m}\cdot\nabla)\mathbf{B} \tag{45}$$

The characteristic force scale for MRFM is 1 atto-newton ($1\ \text{aN} = 10^{-18}\,\text{N}$) set by the interaction between a single electronic moment interacting through a field gradient of $10^5\,\text{T}\,\text{m}^{-1}$ ($1\,\text{G}\,\text{nm}^{-1}$). Detecting the force exerted by a single nuclear spin will require higher field gradients and improved force sensitivity. Detecting such forces is challenging; for comparison, forces measured in conventional SPM are usually not lower than $10^{-12}\,\text{N}$.

The transduction of a force signal into a voltage involves two stages of signal detection: first the mechanical resonator converts the oscillatory force to displacement, then this displacement is detected by a position sensitive readout. Sensitive force detection then requires the following

- System noise should be minimized
  - System noise should be dominated by thermal fluctuations of the cantilever.
  - Noise spectral density and bandwidth should be minimized.
- The signal force must be comparable to or larger than the system noise (referred to the input):

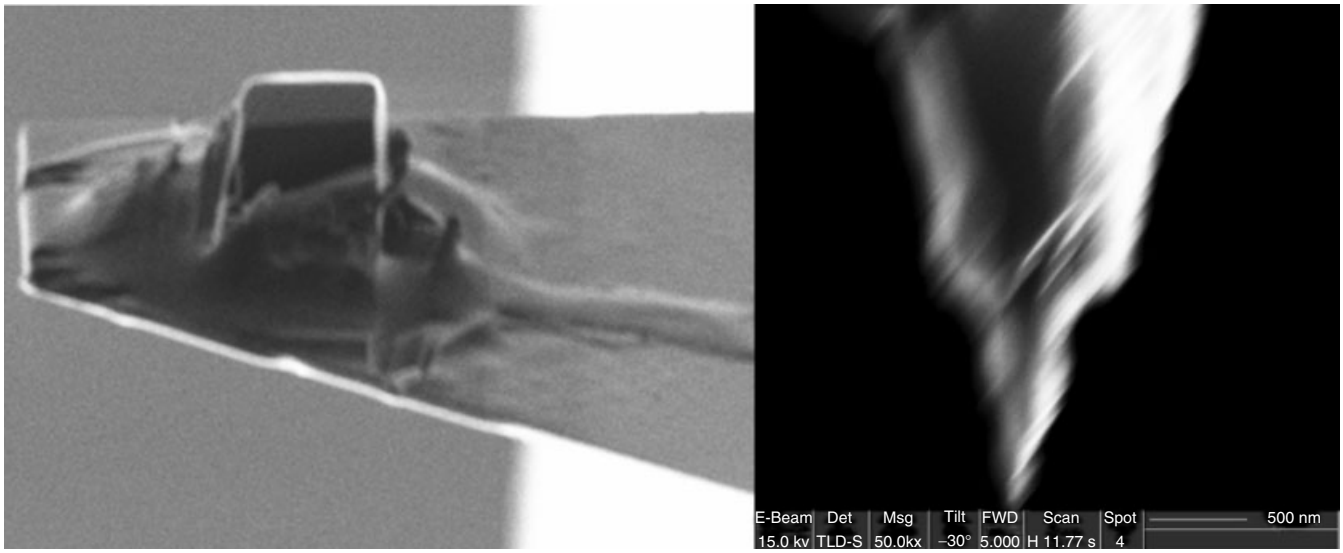

Figure 4. FIB fabricated rare-earth micromagnets (provided by P. Banerjee and R. Steward).

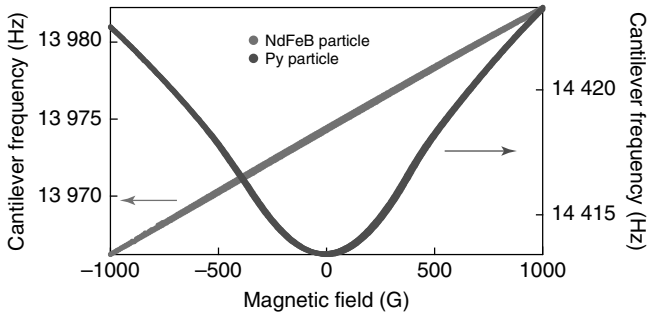

Figure 5. Cantilever magnetometry data for 'hard' NdFeB and 'soft' permalloy probe magnets. The magnetic moment of the particle can be extracted from the slope of the cantilever frequency dependence on the applied magnetic field. It can be seen that, unlike the soft-probe magnet, the hard-probe magnet preserves the direction of its magnetization as the direction of the applied field is reversed. (Provided by P. Banerjee.)

  - The field gradient should be as large as possible.
  - The force signal can be imprinted with an optimal time signature to aid detection and reject nonthermal noise.
- The noise added in reading out the resulting cantilever displacement must be negligible compared to the thermal noise of the cantilever.

This entails engineering the interaction in such a way that the resulting cantilever displacement exceeds both the cantilever displacement noise in the measurement bandwidth and the noise floor of the displacement detection scheme. The readout requirement essentially requires driving the cantilever at its resonant frequency to enhance the oscillation amplitude for a given drive.

4.1 Sensitive oscillatory force detection

The response of a cantilever to an externally applied force is well described by the model of a linear harmonic oscillator. The displacement δz of the end of a cantilever under the influence of a static force F is

$$\delta z_{\text{stat}} = \frac{F}{k} \tag{46}$$

where k is the mechanical spring constant of the cantilever. Thus, a 1 aN force acting on a soft ($k = 10^{-3}\,\text{N}\,\text{m}^{-1}$) cantilever will produce a static displacement $\delta z_{\text{stat}} = 10^{-15}$ m, well below the noise floor of available displacement detection schemes. By driving on resonance, the amplitude of the steady-state oscillations are increased by the quality factor Q:

$$\delta z_{\text{osc}} = Q\frac{F}{k} = Q\delta z_{\text{stat}} \tag{47}$$

Typically Q is $10^4 - 10^5$, resulting in an amplification of the cantilever response sufficient to render displacement readout noise negligible.

4.1.1 Fundamentals of force detection

Force sensitivity for resonant force detectors

The sensitivity of force detection using a micromechanical resonator is ultimately limited by the thermal motion δz_{th} of the resonator. By the equipartition theorem, the average thermal energy per degree of freedom of an SHO is (Albrecht,

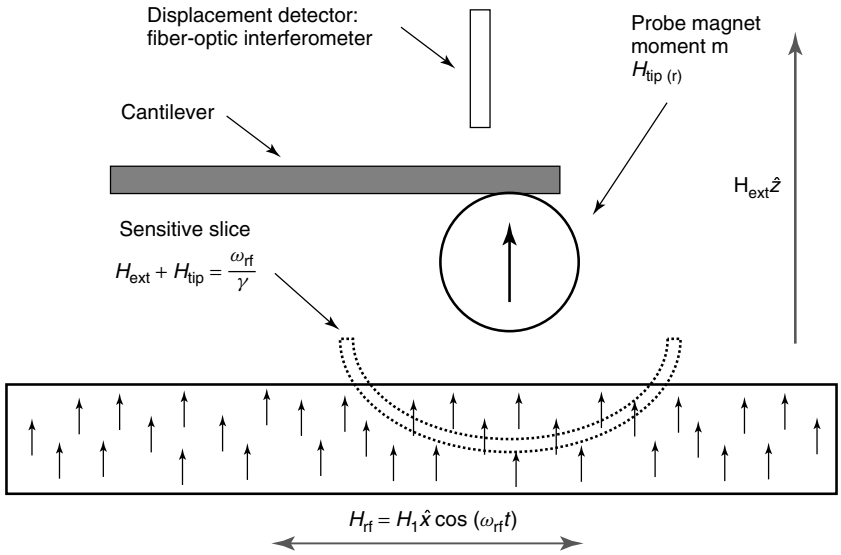

Figure 6. Schematic diagram of an MRFM experiment with probe magnet mounted on the cantilever. The cantilever is parallel to the sample surface. The sensitive slice is shown schematically.

Grutter, Horne and Rugar, 1991)

$$\frac{k\langle\delta z_{\rm th}^2\rangle}{2} = \frac{k_{\rm B}T}{2} \tag{48}$$

Equivalently we can consider the cantilever to be driven by a white noise force $F_{\rm th}$ given by (Stowe *et al.*, 1997)

$$F_{\rm th} = \sqrt{\frac{4kk_{\rm B}T\,\Delta\nu}{Q\omega_c}} \tag{49}$$

where $\Delta\nu$ is the measurement bandwidth. This expression provides a guide to the steps that can be taken to reduce $F_{\rm th}$ such as increasing Q and working at low temperature. In order to be detectable the force arising from the magnetic resonance signal should be greater than $F_{\rm th}$.

Frequency shift detection

It is often convenient, as discussed in the subsequent text, to detect the magnetic resonance signal by measuring the small induced shift in the cantilever resonance frequency ω_c. This approach requires that the cantilever be driven at its resonance frequency; we call the oscillation amplitude $z_{\rm osc}$. The fundamental limit of the sensitivity of frequency detection also arises from the thermal excitation of cantilever. The resulting thermal frequency noise $\delta\omega_{\rm th}$ is given by Albrecht, Grutter, Horne and Rugar (1991)

$$\delta\omega_{\rm th} = \sqrt{\frac{\omega_c k_{\rm B}T\,\Delta\nu}{kQ\langle z_{\rm osc}^2\rangle}} \tag{50}$$

Displacement detection sensitivity

It is important that displacement readout add negligibly to the total detection noise. A resonant oscillatory force of 10^{-18} N acting on a soft ($k = 10^{-3}\,{\rm N\,m^{-1}}$), high Q cantilever will produce cantilever oscillations $\delta z_{\rm osc} \sim 10^{-10} - 10^{-11}$ m. Hence we require displacement readout sensitivity better than $10^{-12}\,{\rm m\,Hz^{-1/2}}$. Thus, displacement sensitivity can be well managed by working at the cantilever resonance frequency.

4.1.2 Amplitude detection

Amplitude detection is the most straightforward approach to MRFM signal detection: a signal force oscillating at ω_c is applied to the cantilever, and the amplitude of the steady-state oscillations, proportional to the applied force, is measured. This approach is the most straightforward to implement and will deliver reliable results in the case of a strong magnetic resonance signal. However, amplitude detection has several disadvantages that complicate its application for high sensitivity measurements. One is the long response time τ (see equation (36) and associated discussion) required for the high Q micromechanical resonator to increase its energy and achieve its steady-state oscillation amplitude. This determines the waiting time between two consecutive signal measurements and thus the rate at which data can be acquired. For a high Q cantilever this time can be as long as 1–10 s, making acquisition of large amounts of data unacceptably time consuming. This problem can be mitigated by using negative feedback (Bruland *et al.*, 1998; Bruland, Garbini, Dougherty and Sidles, 1998) to nondissipatively increase signal bandwidth without increasing $F_{\rm th}$.

Another problem encountered in amplitude detection is the sensitivity of the cantilever frequency to conditions such as the applied field and temperature. This leads to a mismatch between the signal frequency and ω_c thus introducing a spurious variation in the oscillation amplitude that can obscure the desired signal. This is more severe the higher the Q. The solution is to update the frequency ω_{mod} at which the signal force is modulated to match real-time cantilever frequency measurements. This leads naturally to signal detection based on frequency shift detection (Albrecht, Grutter, Horne and Rugar, 1991), a powerful alternative to amplitude detection.

4.1.3 Frequency detection

The magnetic resonance force signal can be transduced into a shift in the cantilever resonance frequency by arranging that the signal force be applied *in phase* with the cantilever position (note that the displacement of a harmonic oscillator driven at its resonance frequency lags the driving force by 90°). Using the equation of motion for an SHO

$$m\frac{\partial^2}{\partial t^2}z + \frac{m\omega_c}{Q}\frac{\partial}{\partial t}z + kz = k_1 z \tag{51}$$

where m is the effective mass of the cantilever and the term on the right side is the signal force $F = k_1 z$, manifestly synchronized with cantilever position z. This requires that the cantilever be separately driven (by means of e.g., a piezoelectric actuator) at its resonance frequency at constant amplitude z_{osc} by means of a positive feedback circuit in which the cantilever is the frequency determining element. The frequency shift is given by

$$\frac{\delta\omega}{\omega_c} = \frac{F}{2kz_{\mathrm{osc}}} \tag{52}$$

The magnitude of F is given by the change in signal force over a half cycle of cantilever oscillation; the frequency shift is

4.2 Spin manipulation protocols

There are several methods that can be used to manipulate spin magnetization at the resonance frequency of the micromechanical force sensor. The choice of a preferred spin manipulation protocol will depend on spin system properties such as relaxation time T_1.

4.2.1 Cyclic suppression

The Bloch equation (25) show that M_z is suppressed by the application of a strong resonant ($\omega_{\mathrm{rf}} = \omega_{\mathrm{L}}$) field H_1. Either shifting the frequency off resonance or reducing the amplitude allows M_z to recover (on a timescale T_1). In order to achieve the goal of modulating M_z at ω_c the magnetization must substantially recover during one period of cantilever oscillation. Hence $1/T_1$ must be larger than ω_{mod}.

Cyclic suppression is straightforward to apply and effective (Zhang, Roukes and Hammel, 1996). Its primary disadvantage arises from the potential for spurious feedthrough forces due to the modulation of the rf field at ω_c. This undesired excitation can easily swamp the magnetic resonance signal which is occurring at the same modulation frequency.

4.2.2 Anharmonic modulation

A solution to this problem (Bruland, Krzystek, Garbini and Sidles, 1995) lies in simultaneous anharmonic modulation of two experimental parameters such as rf field strength and applied magnetic field H_0:

$$H_0(t) = H_0 + H_0^{\mathrm{mod}}\cos(\omega_z t) \tag{53}$$

$$H_1(t) = H_1^0 + H_1^{\mathrm{mod}}\cos(\omega_1 t) \tag{54}$$

with modulation frequencies satisfying $|\omega_z - \omega_1| = \omega_c$. The intrinsic nonlinearity of magnetic resonance leads to a term in the spin magnetization oscillating at ω_c, whereas spurious excitations occur at frequencies far from ω_c and therefore have negligible influence.

4.2.3 Adiabatic inversion

For systems with long spin relaxation times $1/T_1 \ll \omega_{\mathrm{mod}}$ a method based on coherent, periodic rotation of the spin orientation is preferable. This approach is based on the fact that orientation of the magnetization will follow that of $\mathbf{H}_{\mathrm{eff}}$ if $\mathbf{H}_{\mathrm{eff}}$ is rotated sufficiently slowly, that is if the rotation is adiabatic. This amounts to requiring that the magnetization precess many times about $\mathbf{H}_{\mathrm{eff}}$ in the time required to significantly rotate $\mathbf{H}_{\mathrm{eff}}$ itself. $\mathbf{H}_{\mathrm{eff}}$ can be periodically rotated by modulating either the magnitude of external magnetic field H_0 or by frequency modulation (FM) of H_1 (see Figure 1). Initially a spin ensemble is prepared with a thermal equilibrium magnetization $\mathbf{M}_z$ parallel to $\mathbf{H}_0$ and with $\Delta\omega$ sufficiently large that $\mathbf{H}_{\mathrm{eff}}$ is essentially parallel to $\mathbf{H}_0$. The magnetization is inverted by rotating of $\mathbf{H}_{\mathrm{eff}}$ through 180°, that is, $\Delta\omega$ is swept from a large positive value through zero (resonance) to a large negative value. Adiabaticity is determined by the rate of rotation of $\mathbf{H}_{\mathrm{eff}}$ compared to the magnitude of γH_{eff}; which passes through a minimum on resonance where its magnitude is γH_1. The values of $H_1 \sim 1\text{–}10\,\mathrm{G}$ achievable in MRFM set a limit on

the allowed modulation rate $\omega_{\rm mod}$. For inversion by FM the adiabatic condition requires

$$\omega_{\rm mod} \ll \frac{\gamma^2 H_1^2}{\Delta\omega} \tag{55}$$

4.2.4 MRFM excitation by adiabatic reversals

Examination of equation (15) in Section 2.1.4 reveals two ways to modulate the $\hat{z}$-component of $\mathbf{H}_{\rm eff}$: modulation of $\omega_{\rm rf}$ or modulation of $H^{\rm tot}$. We first consider FM to cyclically reverse $\mathbf{H}_{\rm eff}$:

$$\omega_{\rm rf} = \Omega_{\rm FM}\cos(\omega_{\rm mod} t) \tag{56}$$

In order to generate a frequency shift signal the cantilever is driven into oscillation at its natural resonance frequency ω_c with oscillation amplitude $z_{\rm osc}$, and we set $\omega_{\rm mod} = \omega_c$ and phase lock the reversals to the cantilever position (see Section 4.1.3).

Starting with the magnetization parallel to $\mathbf{H}_0$, $\omega_{\rm rf}$ is set to be far below $\omega_{\rm L}$ for the spins of interest (remember that due to the tip field gradient $\omega_{\rm L}$ varies with position). At the moment the cantilever is at an extremum of its oscillation we begin FM centered on $\omega_{\rm L}$ thus generating adiabatic reversals of the magnetization that will shift the cantilever resonant frequency ω_c. This frequency shift is continuously monitored as it decays with time (Figure 7).

The spins will follow $\mathbf{H}_{\rm eff}$ only if it is rotated sufficiently slowly that the adiabatic condition is satisfied, that is, only if spins precess about $\mathbf{H}_{\rm eff}$ much faster than its orientation rotates. The most demanding moment is at resonance when $|H_{\rm eff}|$ is minimum and equal to H_1; typically $\sim$1–10 G in the microwave regime. Hence, the magnitude of H_1 sets the limit on the modulation rate $\omega_{\rm mod}$ achievable with this method. If $\mathbf{H}_{\rm eff}$ is inverted by rf FM the adiabatic condition is

$$\omega_{\rm mod} \ll \frac{\gamma^2 H_1^2}{\Omega_{\rm FM}} \tag{57}$$

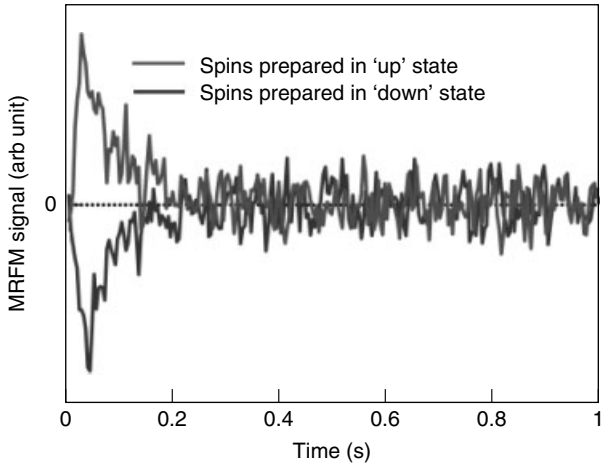

Figure 7. ESR signal at $T = 4$ K from E'-centers in silica detected using OSCAR. The sign of the signal is reversed by preparing the spin system in an inverted state. (Provided by P. Banerjee.)

The lifetime τ_m of the signal generated by cyclic adiabatic inversion cannot exceed the spin relaxation time in the rotating frame $T_{1\rho}$. In practice it is also limited by unavoidable violations of adiabatic condition due to insufficient applied rf field strength H_1.

The sign of the frequency shift can be reversed selecting an opposite sign of the signal force relative to the cantilever position, that is, by reversing the cantilever extremum at which FM is commenced. This allows the sign of the signal to be reversed with minimal change to the spurious background providing a means to subtract off this background.

4.2.5 Oscillating cantilever-driven adiabatic reversals

The technique dubbed oscillating cantilever-driven adiabatic reversals (OSCAR) (Stipe *et al.*, 2001c) was pioneered explicitly for situations where few spins are detected and hence very large gradients are used. OSCAR relies on field modulation in equation (15) to rotate $\mathbf{H}_{\rm eff}$, but uses a clever trick: rather than modulate H_0 advantage is taken of the large field gradient generated by the tip. As the cantilever oscillates this large gradient means that $H_{\rm tip}$ experienced by the spins of interest will be modulated:

$$\delta H_z^{\rm tot} = \delta H_z^{\rm tip} = z_{\rm osc}\frac{{\rm d}H^{\rm tip}}{{\rm d}z} \tag{58}$$

OSCAR naturally inverts the effective field $H_{\rm eff}$ and hence the magnetization with a phase appropriate for frequency shift detection: because the modulation of the field is due to cantilever motion the oscillations are perfectly synchronous with the position of the cantilever (see Figure 1). Consequently, as long as the adiabatic condition (equation (57)) is satisfied the force on the cantilever will be explicitly phase-locked to the position of the cantilever and so the force will shift the resonance frequency of the cantilever.

The OSCAR protocol also begins with the magnetization polarized along $\mathbf{H}_0$. The rf field with its frequency $\omega_{\rm rf}$ well below $\gamma H_{\rm tot}$ is turned on when the cantilever is at an extremum so the effective field $\mathbf{H}_{\rm eff}$ is nearly aligned with $\mathbf{H}_0$. The tip motion will modulate the field causing adiabatic reversals that shift ω_c.

The sign of the frequency shift depends on the phase of the cantilever oscillations relative to the magnetization reversals again providing a means to subtract off spurious backgrounds. This relative phase can be changed, for example, by

preparing spins in a state aligned in the direction opposite to $\mathbf{H}_0$ by means, for example, of an rf π pulse such as is shown in Figure 7. This enables detection of the spin polarization state using MRFM.

We return to the requirement OSCAR places on the field gradient. Successful adiabatic reversal requires $\Delta H_{\mathrm{tot}} \gg H_1$, and since $\Delta H_{\mathrm{tot}} = z_{\mathrm{osc}} \mathrm{d}H^{\mathrm{tip}}/\mathrm{d}z$ we need

$$\frac{\mathrm{d}H^{\mathrm{tip}}}{\mathrm{d}z} \gg \frac{H_1}{z_{\mathrm{osc}}} \tag{59}$$

It is unproductive to make z_{osc} much larger than 100 nm because this reduces the frequency shift (see equation (52)), so for $H_1 \sim 1$–10 G, gradients of order of 0.1–$1\,\mathrm{G\,nm^{-1}}$ are needed.

4.3 Probe–sample interactions

The MRFM probe–sample interaction is given by equation (45). Though this expression is convenient it fails to convey many salient features of the general case. Let us consider a probe magnet creating a spatially nonuniform magnetic field $\mathbf{H}^{\mathrm{tip}}(\mathbf{r})$, where $\mathbf{r}$ is the spatial coordinate, interacting with a time dependent spin magnetization of the sample $\mathbf{m}(\mathbf{r}, t) = \mathbf{m}_0(\mathbf{r}) + \delta\mathbf{m}(\mathbf{r}, t)$ with the time dependent component originating from rf manipulation of spins in the sample. In this case, the time dependent component of the total force between the MRFM probe and the sample will be

$$\mathbf{F}(t) = \int_V (\delta\mathbf{m}(\mathbf{r}, t) \cdot \nabla)\, \mathbf{B}^{\mathrm{tip}}(\mathbf{r})\, \mathrm{d}\mathbf{r} \tag{60}$$

where the integration done over the entire sample volume. The static component of the interaction with $\mathbf{m}_0(\mathbf{r})$ will not be detected by the resonant detection scheme employed in MRFM. To understand MRFM probe–sample interaction, we must analyze the spatial and time dependence of $\delta\mathbf{m}(\mathbf{r}, t)$ and the spatial variation of the gradient of the magnetic field $\mathbf{H}(\mathbf{r})$ of the micromagnetic tip.

4.3.1 Sensitive slice evolution

The spatial variation of $\delta\mathbf{m}(\mathbf{r}, t)$ will depend on the method used for spin manipulation. As an illustrative example we consider the case of cyclic suppression (Section 4.2.1) by means of a 100% amplitude modulation of the intensity of the rf field. The frequency of the rf radiation is ω_{rf}. For simplicity, we assume that the sample is placed in the external magnetic field $\mathbf{H}_0 \parallel \hat{z}$ such that $|\mathbf{H}_0| \gg |\mathbf{H}^{\mathrm{tip}}(\mathbf{r})|$. The thermal spin polarization in this case is $\mathbf{m}_0 = m_0\hat{z}$. The probe magnet is a small magnetic sphere magnetized in the $\hat{z}$ direction. The (spatially dependent) response of the magnetization to the applied rf field is given by equation (25); we find

$$\delta m_z(\mathbf{r}) = \frac{m_0\gamma^2 H_1^2 T_1 T_2}{1 + [T_2(\gamma\left|\mathbf{H}_0 + \mathbf{H}^{\mathrm{tip}}(\mathbf{r})\right| - \omega_{\mathrm{rf}})]^2 + \gamma^2 H_1^2 T_1 T_2} \tag{61}$$

This equation shows that the applied rf radiation will have the greatest effect on the spins in the spatial volume known as the *sensitive slice* where the following condition is satisfied:

$$\left|\gamma\left|\mathbf{H}_0 + \mathbf{H}^{\mathrm{tip}}(\mathbf{r})\right| - \omega_{\mathrm{rf}})\right| \leq \frac{\delta\omega}{2} \tag{62}$$

Here $\delta\omega = T_2^{-1}$ is the linewidth of the magnetic resonance signal (see equation (25)). The shape of the sensitive slice, a bowl centered on the probe magnet, is defined by both $\mathbf{H}_0$ and $\mathbf{H}^{\mathrm{tip}}(\mathbf{r})$; this shape is shown in Figure 8 for various values of H_0. The radius of the bowl increases with increasing $|\mathbf{H}_0|$ until it transforms into a doughnut-like shape when $|\mathbf{H}_0| > \omega_{\mathrm{rf}}/\gamma$.

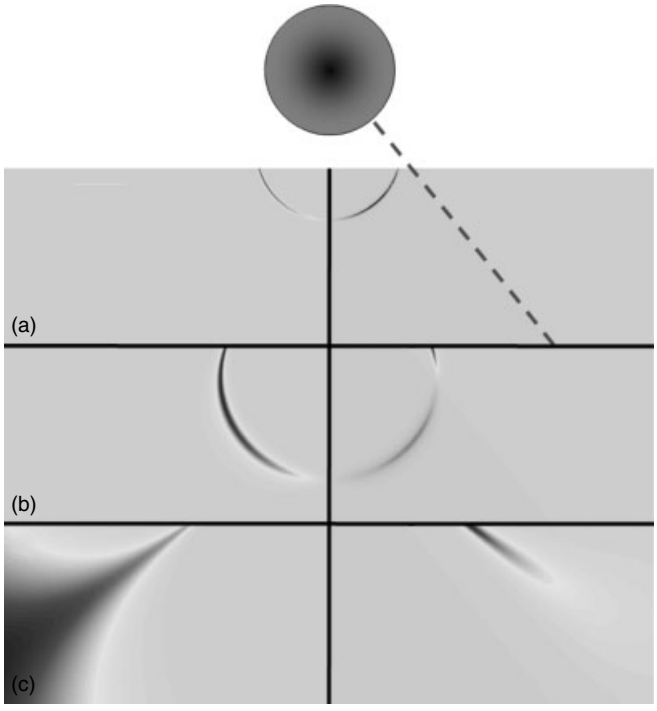

Figure 8. Evolution of the sensitive slice (left panel) and the force slice (right panel) with applied field H_0 increasing from (a) to (c), with (c) corresponding to $H_0 = \omega_{\mathrm{rf}}/\gamma$. The probe magnet of diameter a (shown as the black circle above the sample) and the magnet-sample separation are presented to scale, with the sample width being $5\,a$. The dashed line marks the line of the zero gradient $\mathrm{d}H_z/\mathrm{d}z$. (A color version of this figure is presented in Suter, Pelekhov, Roukes and Hammel, 2002.) (Reprinted with permission A Suter *et al*., copyright 2002, Elsevier.)

4.3.2 Evolution of the force

The magnetization couples to the cantilever through the $\hat{z}$ component of the force $-(\mathbf{m}\cdot\nabla)\mathbf{B}(\mathbf{r})$, hence for the geometry shown in Figure 6 the component of primary interest is $\mathrm{d}H_z/\mathrm{d}z$. The dipolar nature of the probe field means the sign $\mathrm{d}H_z/\mathrm{d}z$ reverses for magnetization off to the side of the tip (see Figure 8), therefore different parts of the sample contribute forces of different sign and, under certain conditions, can cancel one another. Figure 8 shows the evolution of the 'force slice' which is essentially the 'sensitive slice' convolved with the position dependence of the tip gradient. Spins located along the lines of zero gradient do not contribute to the interaction.

4.3.3 Leading edge signal

The spectrum, that is, the evolution of the signal force with field H_0, can be simulated by integrating the force over the entire sample for a series of applied fields. It is typical that the signal changes sign as the shape of the sensitive slice evolves with H_0 (Suter, Pelekhov, Roukes and Hammel, 2002). An important feature of the spectrum is its 'leading edge', that is, the minimum field H_0 at which the signal appears; this occurs as the sensitive slice just enters the surface of the sample. The field offset of this feature from $\omega_{\mathrm{rf}}/\gamma$ measures the strength of the field due to the probe magnet for a particular tip-sample separation.

Measuring the tip field as a function of separation is useful for mapping the spatial variation of tip field with nanometer scale resolution. From this the gradient of the tip field can be accurately obtained. Precise characterization of MRFM probe magnets is essential for correct interpretation of MRFM data.

5 APPLICATIONS

MRFM is a powerful and inventive approach to imaging and characterization of a broad variety of materials. As in the case of conventional magnetic resonance, MRFM is based on direct coupling of the detector to the dipole moment of the target spin. As we have seen in the preceding text because this interaction is quite weak this entails great care in the detection of the signal and has implications for quality and bandwidth of the signal detected. On the other hand, this allows the approach to be applicable to the detection of any spin or spin ensemble that can be brought into the proximity of the micromagnetic probe tip. This excellent breadth of applicability and flexibility distinguishes it from the array of powerful spin sensitive detection techniques currently in use and development.

The true power of MRFM will be determined by the impact of its application to problems studying and developing electronic, magnetic, and structural materials as well as to the biomedical community with extensive need for structural and functional characterization and visualization of biological materials. The rapid pace at which MRFM has improved capabilities such as sensitivity, signal bandwidth, and the rapidly expanding range of materials to which it has been successfully applied suggest a robust technique with the broad flexibility necessary to adapt to the diversity of experimental conditions that will be encountered in performing compelling studies of currently interesting materials.

MRFM offers the excellent sensitivity required to achieve very high spatial resolution. Just as important, this excellent sensitivity comes with a noninvasive probe that will benefit fields from nano-electronics to biomolecular imaging. As electronic elements become smaller, they become sensitive to even individual impurities and dopants; hence three-dimensional atomic scale characterization becomes crucial. Perhaps most notably, the field of spin-based quantum computation will require single spin detection technology both for quantum state readout and for device characterization; single spin MRFM promises to aid in this challenging undertaking.

5.1 Ferromagnetic resonance

There are two motivations for performing FMR experiments using the MRFM. First is the tremendous promise of microscopic FMR experiments for elucidating the nature of scientifically and technologically important magnetic materials such as layered magnetic systems exploiting spin dependent electron transport phenomena. It is important to understand how the performance of such devices is influenced by microscopic spatial variations in properties like interface quality, exchange coupling, and magnetic anisotropy. Conventional FMR has proved to be a powerful technique in evaluating the average values of these properties within the sample.

With the addition of the microscopic imaging capability of MRFM, FMR/MRFM could become one of the primary characterization techniques for such devices (see Wigen, Roukes and Hammel, 2006) for a review of FMR microscopy. Furthermore, unlike conventional inductive detection force detection of magnetic resonance is uniquely sensitive to M_z, the longitudinal component of the magnetization. In the subsequent text, we outline some experiments that exploit these strengths and demonstrate the potential MRFM holds for studies of ferromagnetic materials and devices.

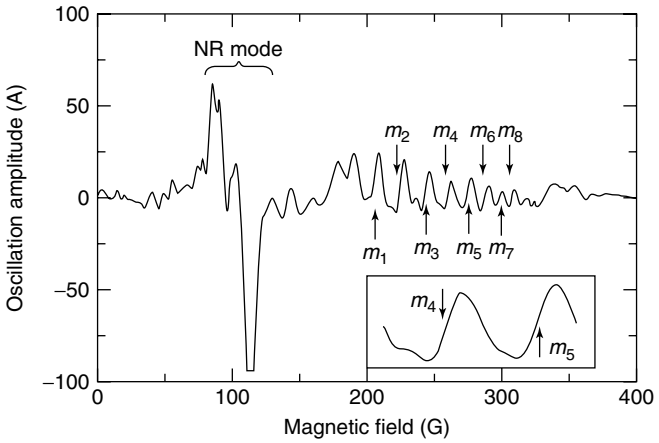

Figure 9. An experimental FMR/MRFM spectrum (cantilever oscillation amplitude as a function of applied field in Gauss) of a single crystal YIG film (Reprinted with permission Z Zhang *et al*., copyright 1996, American Institute of Physics.) which shows the nonresonance (NR) mode and a family of magnetostatic modes (labeled m_1, m_2, ...). The locations of the magnetostatic modes are indicated by arrows in the inset. The resonance was excited by a 2 G, 825 MHz magnetic field; the rf field was 100% amplitude modulated at 41.27 kHz. The bias field was ramped at $1.5\,\mathrm{G\,s^{-1}}$ and modulated at a frequency of 36.01 kHz and with a modulation amplitude of 4 G.

5.1.1 MRFM detection of FMR

The first MRFM detection of FMR (see Figure 9) was demonstrated on a film sample of yttrium iron garnet (YIG) by Zhang, Hammel and Wigen (1996). The sample was an approximately rectangular parallelepiped $20 \times 40 \times 3\,\mu\mathrm{m}^3$ YIG chip that was mounted on the cantilever; the gradient magnet was stationary. The signal was sufficiently large that the experiments were performed in ambient air to reduce Q and the cantilever's oscillatory response. The signal was generated by anharmonic modulation (Bruland, Krzystek, Garbini and Sidles, 1995). The applied magnetic field ranged from 150 to 400 Oe, so the sample was not entirely saturated. As a consequence strong spurious coupling was observed at lower fields where the field was just sufficient to saturate the center of the sample, so modulation of the field significantly altered M_z.

At higher fields, a family of resonance modes, the magnetostatic modes first calculated by Damon and Eshbach (DE) (1961) were observed. The application of DE theory was complicated by the small size and irregular shape of the sample and by the fact that the sample is not fully saturated at resonance. Nonetheless, the results agreed qualitatively with estimates based on DE theory in a rectangularly-shaped, saturated YIG medium. The tip field strength was insufficient to enable local imaging, so the resonance modes observed arose from the resonance behavior of the entire sample.

Wago, Botkin, Yannoni and Rugar (1998) performed FMR on a similar sample, but with gradients as large as $10\,\mathrm{G\,\mu m^{-1}}$ and found similar behavior, namely, that the detected modes were collective modes of the entire sample defined by sample dimensions. Images consistent with this conclusion were observed.

5.1.2 Damping in ferromagnets

Klein and coworkers have performed experiments in which they used MRFM to perform FMR experiments on a 160 μm diameter YIG disk (Klein, Charbois, Naletov and Fermon, 2003; de Loubens, Naletov and Klein, 2005). They exploited both the fact that force detection is sensitive to the longitudinal component of the magnetization rather than the transverse component as in inductive detection and the high sensitivity of MRFM to allow measurements not possible by conventional means. Their measurements were performed on the entire YIG disk with the tip far removed. This work has provided quantitative results that provided unique insights into fundamental dynamic behaviors in ferromagnets.

MRFM detection of FMR differs from conventional approaches in that M_z is directly measured in contrast to measurement of the absorption of microwave power as in conventional FMR detection. They compared power absorbed (proportional to the square of the transverse magnetization M_t^2) to M_z to identify various contributions to the observed FMR linewidth. The enhanced sensitivity provided MRFM detection also allowed detection of the longitudinal moment across a broad range of microwave frequencies even far from the resonance frequency of the microwave resonator.

Their MRFM measurement of the FMR linewidth as a function of frequency from 5 to almost 14 GHz revealed a linear response, that a frequency dependent component and a frequency independent component. The frequency dependent component that is associated with Gilbert damping because of the proportionality to $\partial M/\partial t$, while frequency independent component can have various origins including inhomogeneous broadening and impurity scattering of magnons. The frequency dependence revealed a peak in the linewidth at the resonant frequency of the microwave resonator that was attributed to loading of the resonator by the sample so as to reduce the intensity of H_1 near the Larmor frequency.

While providing insight the homogeneous and inhomogeneous contributions to the linewidth cannot be distinguished on the basis of the frequency dependence alone. It is known that by measuring the dependence of the FMR signal amplitude on the frequency at which the microwave excitation frequency is modulated the relaxation times associated with relaxation via magnetostatic and exchange modes can be

extracted. MRFM detection of the longitudinal magnetization as a function of modulation frequency was used for this measurement in addition to traditional FMR techniques to measure the dependence of the transverse magnetization on the same quantity. For MRFM detection the signal must be generated at ω_c (see Section 4); in order to allow modulation at a broad range of frequencies, Klein *et al*. employed anharmonic modulation (Bruland, Krzystek, Garbini and Sidles, 1995) involving simultaneous frequency and amplitude modulation (at ω_a) of the microwave excitation such that $\left|\omega_f \pm \omega_a\right| = \omega_c$.

The group took advantage of MRFM's unique ability to directly measure M_z They observed a rapid suppression of M_z as saturation of the resonance is approached. This provides new insight into the spin dynamics occurring at saturation. Spin relaxation arises from the generation of spin waves (Suhl and Phys, 1957; Fletcher, LeCraw and Spencer, 1960), but the transverse magnetization is largely insensitive to short wavelength spin wave modes because their transverse component averages to zero, so only measures the number of fundamental mode spin waves. However each spin wave mode reduces the longitudinal magnetization by $\gamma\hbar$ so the longitudinal magnetization measures the total number of spin waves of all wavelengths. As shown in Figure 10, at saturation $1/T_1$ decreases rapidly as the generation of fundamental mode spin waves saturates. Instead there is a rapid increase in the generation of short length spin waves that cannot be detected in conventional transverse linewidth measurements.

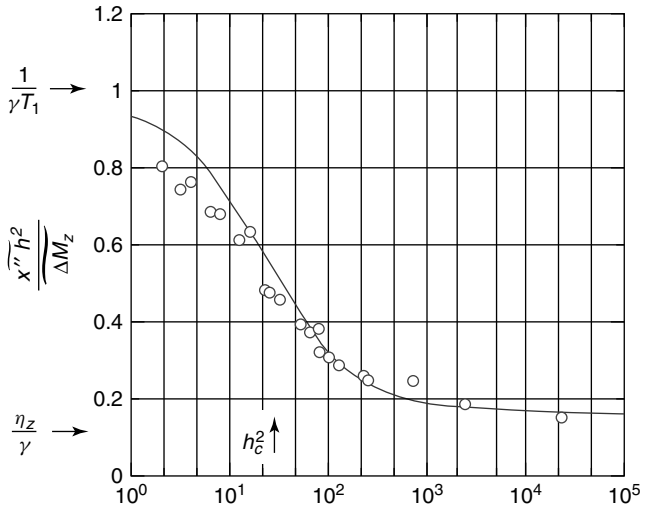

Figure 10. A plot of the ratio of the transverse component of the magnetization relative to the longitudinal component versus microwave power. (Reprinted with permission de Loubens *et al*., copyright 2005, American Physical Society.) This ratio is equal to $1/\gamma T_1$. By comparing conventional and MRFM detected linewidth data, the authors showed the rapid decrease of $1/T_1$ at saturation.

5.1.3 FMR imaging

Mewes *et al*. have demonstrated the ability of MRFM to observe spin dynamics of ferromagnets in micron-scale ferromagnetic structures (Mewes *et al*., 2006). The experiments were performed on an array of permalloy disks 50 nm thick and 1.5 μm in diameter. Experiments were performed both with the tip far from the dots and very close. When distant the tip field was very small and magnetostatic modes in good agreement with theoretical expressions (Kalinikos, 1980) were observed. The MRFM tip used was characterized by means of ESR experiments on DPPH (1,1-Diphenyl-2-picrylhydrazyl) to determine the dependence of the tip field on tip-sample separation.

The sample experiences tip fields in excess of 400 Oe when the tip approaches closely. The external magnetic field was tuned to the spectral feature associated with the fundamental magnetostatic mode and the tip was scanned over the sample (Figure 11). The resolution of the image is much better than that achievable using the same tip (tip width ~1 μm) for MFM of the dots. In fact the spatial resolution is roughly consistent with the ratio of the linewidth of the mode selected for imaging (~40 Oe) and the field gradient (~300 G μm^{-1}); the same ratio that sets spatial resolution in MRI of paramagnetic materials. Thus MRFM allows studies of static and dynamic spin properties in patterned magnets with resolution not set by the tip dimensions as in MFM. However the detailed mechanism of imaging is not understood and the question of spatial resolution achievable in extended ferromagnets remains an area of active study (Mewes *et al*., 2006; Midzor *et al*., 2000; Urban *et al*., 2006).

5.2 Electron spin resonance

Mechanical detection of magnetic resonance was first demonstrated using ESR (Rugar, Yannoni and Sidles, 1992) using an organic molecule DPPH with an unpaired spin that has a rapid (and temperature independent) spin relaxation rate ($T_1 \approx T_2 \approx 60$ ns) and a high spin density (2×10^{21} cm^{-3}). Because $\omega_c \ll 1/T_1$ cyclic suppression must be used to modulate M_z (see Section 4.2.1).

The push to improve detection sensitivity has relied on samples with very long spin relaxation times ($\gg \omega_c^{-1}$) to enable long data collection times and therefore reduced noise bandwidths. In this case, modulation of M_z is accomplished by means of cyclic adiabatic inversion (Section 4.2.3).

That effort produced the milestone of MRFM detection of a single electron spin by (Rugar, Budakian, Mamin and Chui, 2004). This is a signal achievement that dramatically alters the horizons for high-resolution imaging and experimentation on nanoscale systems. It confirms the extraordinary sensitivity of MRFM and underlines the breadth and flexibility of

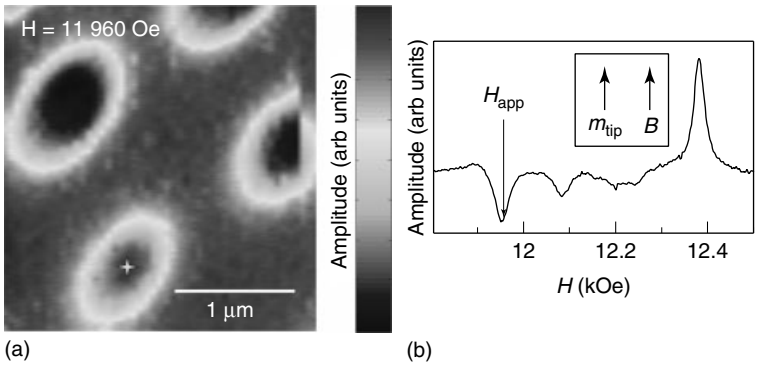

Figure 11. Images obtained at a tip-sample separation of 150 nm and a microwave frequency of $f_{mw} = 7.7\,\text{GHz}$ 60% amplitude modulated at the cantilever frequency are shown. (b) shows the MRFM spectrum obtained with the tip located over the center of the permalloy dot (indicated by the star). (a) shows the cantilever response obtained in lateral scans over an area $2.5 \times 2.5\,\mu\text{m}^2$ at a field $H = 11\,960\,\text{Oe}$. The external magnetic field was aligned parallel to the moment of the tip.

the method. The experiment was done on a silica sample containing a low density ($\sim 10^{14}\,\text{cm}^{-3}$) of electronic spins known as E′ centers that are created by γ-irradiation of the silica. The low spin density ensured that an isolated spin could be found for detection by the MRFM micromagnetic tip.

5.2.1 Single electron spin detection

The ultrahigh sensitivity regime involves several extreme parameter values that lead to new phenomena:

- Very high sensitivity enables detection of ensembles sufficiently small that the thermal fluctuations of the net spin polarization dominate over the thermal equilibrium polarization.
- The large tip field gradients necessary for high sensitivity lead to large temporal variations of the magnetic field as a consequence of cantilever motion; these can be beneficial or detrimental.

Statistical spin polarization

For sufficiently small ensembles thermal fluctuations of the net spin polarization can be an important effect: the net spin polarization is proportional to

$$\Delta N = N_\uparrow - N_\downarrow = \sqrt{N} \tag{63}$$

This 'statistical polarization' becomes comparable to the thermal equilibrium Boltzmann polarization at $T = 4\,\text{K}$ and $H = 1\,\text{kOe}$ for samples containing of order 10^4 spins. One can then achieve larger signals and can collect data continuously avoiding the need to wait for the spin polarization to recover to thermal equilibrium by means of spin-lattice relaxation before the next measurement.

On the other hand the average polarization and hence average signal is zero, and so the spin magnetic resonance response is manifested only in the variance of the force signal (Budakian, Mamin, Chui and Rugar, 2005). Instead of a definite frequency shift the cantilever undergoes random frequency fluctuations (see Figure 12) of magnitude

$$\delta f_c = \pm f_c \frac{2\mu_B \sqrt{N} \nabla H_z}{\pi k z_{osc}} \tag{64}$$

With field gradient $\nabla H_z \approx 2\,\text{G nm}^{-1}$ and a very small cantilever spring constant $k \approx 0.1\,\text{mN m}^{-1}$ the frequency shift per electronic spin is $\sim$3–5 mHz assuming $z_{osc} = 16\,\text{nm}$.

Interrupted OSCAR

This challenge led to the development of a variant of the OSCAR (Rugar, Budakian, Mamin and Chui, 2003) technique (Section 4.2.5) in which the motion of the micromagnetic tip mounted on the driven cantilever cyclically reverses the orientation of H_{eff} and hence the spin orientation. Dubbed iOSCAR (Mamin, Budakian, Chui and Rugar, 2003) it employs an interruption of the rf field for half a cantilever period that allows the cantilever to move from one extremum to another without rotating H_{eff}. The spin force remains proportional to the cantilever position, but the phase of the oscillatory force exerted on the cantilever relative to its position is reversed thus changing the sign of the resulting frequency shift (see Figure 13). This modulates the OSCAR signal and imprints the signal with a time signature that allows it to be identified at nonzero offset frequency from $f_c = \omega_c/2\pi$.

If the rf power is interrupted at a frequency $f_{int} = 86\,\text{Hz}$ the cantilever frequency is modulated at $f_{sig} = f_{int}/2 = 43\,\text{Hz}$. The frequency shift associated with the magnetic

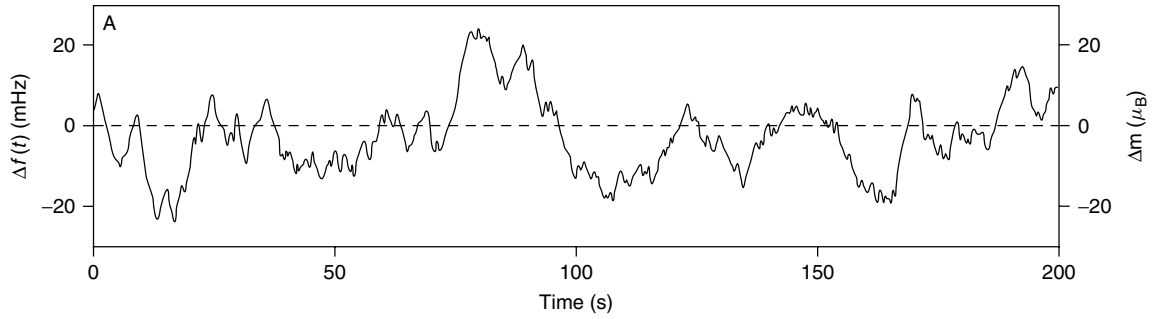

Figure 12. Trace showing a time record of the statistical fluctuations. (Reprinted with permission Budakian *et al*., copyright 2005, AAAS.) The frequency shift recorded in a 83-mHz bandwidth is converted to equivalent number of spins (right-hand axis) by dividing Δf by the average frequency shift per spin ($\overline{|\delta f|} = 0.8$ mHz/spin).

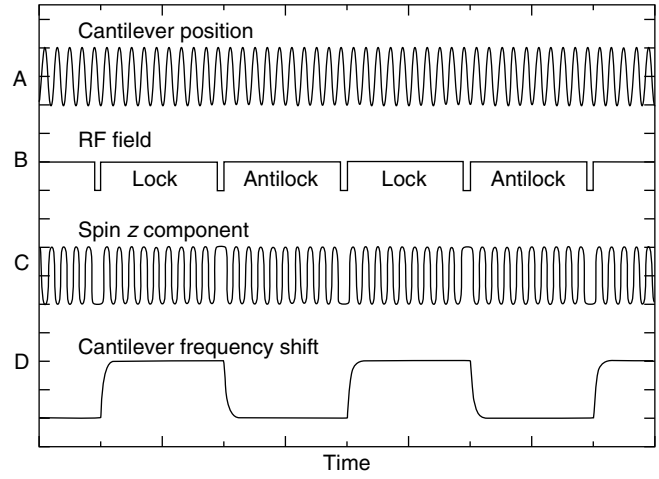

Figure 13. Timing diagram for the interrupted OSCAR protocol. (Reprinted with permission Mami *et al*., copyright 2003, American Physical Society.) The cantilever is oscillated continuously at its resonance frequency, and the microwave field (curve B) is normally on, but is periodically interrupted for one-half cantilever cycle. The z component of the magnetization (C) oscillates in response to the cantilever motion due to adiabatic rapid passage when the microwaves are on, but is left static when they are off. The oscillating magnetization reverses phase with respect to the cantilever for each microwave interruption, giving a cantilever frequency shift (D) that oscillates at one-half the microwave interrupt frequency (F).

resonance alone will manifest itself at this frequency with an intensity

$$\Delta f(t) = \frac{4}{\pi}|\delta f_c|A(t) \tag{65}$$

where $A(t)$ represents the random statistical fluctuations (Rugar, Budakian, Mamin and Chui, 2004).

Signal averaging presents an unusual challenge in this case since the average signal is zero: $\langle A(t)\rangle = 0$, hence $\langle \Delta f(t)\rangle = 0$, and $\langle [A(t)]^2\rangle = 1$. Hence to obtain a signal the square of the frequency shift $[\Delta f(t)]^2$, that is, the signal energy (Rugar, Budakian, Mamin and Chui, 2004) was detected. The phase sensitive lock-in detection can be adjusted such that the signal force appears only in the in-phase variance of the measured signal can be written as $\sigma_I^2 = \sigma_{\text{spin}}^2 + \sigma_{\text{noise}}^2$, where σ_{spin}^2 and σ_{noise}^2 are uncorrelated variances of the spin signal and the noise respectively; the quadrature variance σ_Q^2 will then contain only noise, that is, $\sigma_Q^2 = \sigma_{\text{noise}}^2$. The spin signal is $\sigma_{\text{spin}}^2 = \sigma_I^2 - \sigma_Q^2$ and the signal-to-noise ratio $\text{SNR} = \sigma_{\text{spin}}^2/\sigma_I^2$.

Using this technique the signal from a single electron spin was detected. The low spin density of the sample provides for a 200–500 nm spacing between the spins, whereas while the detected spin sufficiently dilute that the probe can interact only with one spin at a time (see Figure 14). The force variance was $|\delta f_c| = 4.2$ mHz in very good agreement with the expected value. The consistency spatial shift of the signal with change of microwave frequency and the expected value of the force signal variance verified that the signal originates indeed from a magnetic resonance signal.

5.2.2 *Spin relaxation by thermal motion of high gradient tip*

The lifetime of a spin signal during a cyclic inversion measurement is a crucial parameter as short lifetimes spread the signal in frequency space requiring wider bandwidth and hence increased noise. Sensitive experiments require close approach of the magnetic tip to the spin to be detected, but early ESR MRFM experiments showed substantial reduction of the rotating frame electron spin relaxation time τ_m as the tip approached the spin. Rugar *et al*. found that τ_m was reduced from 275 ms to 68 ms as the tip-spin spacing was reduced from 1500 nm to 800 nm (Stipe *et al*., 2001c).

The excess relaxation was found to arise from the magnetic field fluctuations that result when thermal vibrations displace the high gradient tip (Mozyrsky, Martin, Pelekhov and Hammel, 2003). As discussed in Section 2.1.3 the component of

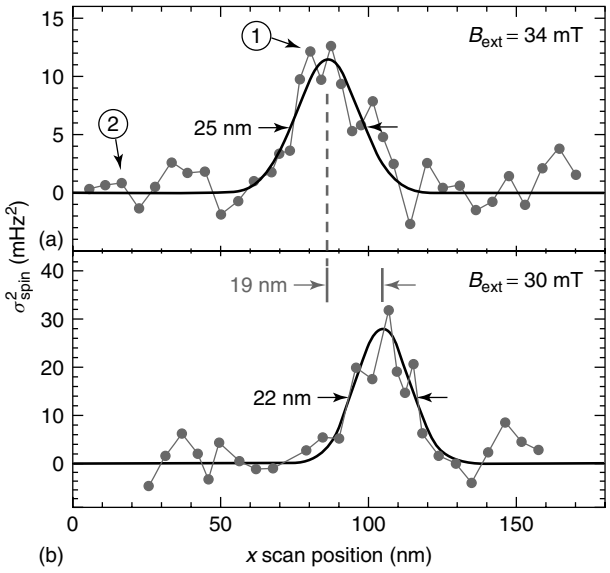

Figure 14. A graph (Reprinted with permission D Rugar *et al*., copyright 2004, Nature Publishing Group.) showing the spin signal as the probe magnet is scanned laterally in the **x** direction across a single electron in a SiO_2 for two values of external field: (a), B_{ext} = 34 mT, and (b), B_{ext} = 30 mT. The smooth curves are Gaussian fits to guide the eye. The 19 nm shift in peak position reflects the movement of the resonant slice induced by the 4 mT change in external field. The difference in absolute peak height is primarily due to different lock-in amplifier detection bandwidths: 0.18 Hz and 0.59 Hz for (a) and (b), respectively.

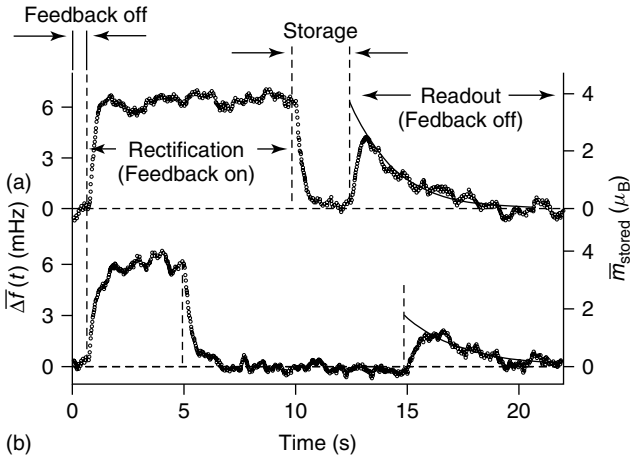

Figure 15. Control of the spin magnetization of few spin ensembles using MRFM (Reprinted with permission Budakian *et al*., copyright 2005, AAAS.) is shown. (a) An average polarization of about 3.7 μ_B was created in an ensemble of $N \approx 70$ spins through active feedback, stored in the laboratory frame for 2.5 seconds, and subsequently read out. (b) Data taken under the same conditions as (a) except that the storage time has been extended to 10 s.

these transverse magnetic field fluctuations at the Larmor frequency ω_L will induce spin relaxation. During the adiabatic inversion the magnetization precesses at frequency $\omega_L(t) = \gamma H_{eff}(t)$; the minimum frequency will be $\omega_L = \gamma H_1$, corresponding to a precession frequency of $\omega_L/2\pi \approx 3$–10 MHz. Though the fundamental cantilever mode is at $\omega_c/2\pi$, typically in the range 1–10 kHz, higher cantilever harmonics can significantly contribute to spin relaxation. It was shown (Mozyrsky, Martin, Pelekhov and Hammel, 2003; Berman, Gorshkov, Rugar and Tsifrinovich, 2003) that the electron spin relaxation rate due to the higher order cantilever modes is

$$\frac{1}{\tau_m} \approx \frac{3.4\mu_B \nabla \mathbf{H}_{probe}}{\hbar} \left(\frac{k_B T}{k\sqrt{z_0^2 - z_1^2}} \right) \left(\frac{\omega_c}{\gamma H_1} \right)^{3/2} \qquad (66)$$

where z_0 is the amplitude of thermal cantilever motion, z_1 is the tip-sample separation, k is the cantilever spring constant and T is temperature. As the probe is brought close to the sample the strength of the probe field gradient $\nabla \mathbf{H}_{probe}$ and hence the induced relaxation rate increases. It is noteworthy that increasing H_1 also reduces excess relaxation.

This problem was conclusively addressed in the single spin experiment (Rugar, Budakian, Mamin and Chui, 2004) where a cantilever designed with an extra mass at its tip to suppress high order vibrational modes effectively eliminated the excess relaxation (Chui *et al*., 2003). H_1 intensity was increased to 7 G through use of a superconducting microwave circuit (Mamin, Budakian and Rugar, 2003). As a result the rotating frame electron spin relaxation τ_m of a single electron was estimated to be 760 ms in the tip field gradient of 2.0 G nm^{-1} ≈250 nm away from the detected spin.

5.2.3 Creating order in spin ensembles

Complementary to high-resolution imaging is the ability MRFM provides to controllably manipulate spin magnetization using spatially localized magnetic resonance. This kind of close control has been nicely demonstrated in experiments that have built on the high sensitivity ESR detection (Budakian, Mamin, Chui and Rugar, 2005).

The first experiment involved hyperpolarizing an electron spin ensemble by capturing an especially large statistical fluctuation (Budakian, Mamin, Chui and Rugar, 2005). In this experiment, the cantilever signal frequency shift $\Delta f(t)$ was continuously monitored, and when the frequency shift exceeded a certain threshold value the rf field was turned off (see Figure 15). Without an rf field cantilever electron spins remain oriented along $\hat{\mathbf{z}}$ and are unaffected by cantilever oscillation so their polarization is effectively preserve for times of order T_1 (measured to be ≈30 s). Spin polarization exceeding anything achievable by thermal polarization could be generated and used in other experiments.

The second experiment building on this idea controlled the spin dynamics of the through real-time feedback. Whenever the frequency shift fell below a certain value a π-inversion was applied. This prevented the system from evolving beyond the predefined polarization. By this means the spin system was locked into a relatively well defined polarization state.

5.3 Nuclear magnetic resonance

NMR is a powerful tool for material studies. Nuclear spins are prevalent in most materials and chemical specificity is achieved since each nuclear spin has a unique gyromagnetic ratio. This has made high sensitivity MRFM detection of NMR a key goal. Excellent progress has been made since the first detection of NMR by means of MRFM in 1993 (Rugar *et al*., 1994).

5.3.1 Detection and manipulation of statistical polarization

State-of-the-art sensitivity has been demonstrated in an experiment (Mamin, Budakian, Chui and Rugar, 2005) that detected the statistical spin polarization of nuclear spins. Nuclear moments are $\sim 10^3$ times smaller than electronic moments, so this approach requires very high sensitivity. The ability to achieve substantial polarization without waiting T_1 is even more advantageous than for electron spin detection because nuclear T_1s can exceed hours at low temperatures.

Three nuclear spin systems were used in this study: ^{19}F nuclei in CaF_2, and ^{1}H spins in the polymer polymethylmethacrylate (PMMA) and collagen. The CaF_2 experiment demonstrated spin sensitivity of $\approx$2000 nuclear spins with a 2.5 h averaging time.

Techniques based on short rf pulses inserted into the interrupted OSCAR protocol described in Section 5.2.1 were developed for spin nutation and transverse spin relaxation measurements using statistically polarized spin ensembles. During the nutation experiment, an rf pulse of length t_p was inserted during the cantilever cycle when the nuclear spins are precisely on resonance causing them to precess about the $\mathbf{H}_{\text{eff}}$ which lies in the $\hat{x}$ plane in the rotating frame of reference. As the pulse length, and therefore the angle of spin rotation, is changed the signal oscillates with period $T = 2\pi/\gamma H_1$ as shown in Figure 16.

The inhomogeneous transverse spin relaxation time measurement is similar but is based on sequence of two $\pi/2$ pulses separated by a time τ inserted into the iOSCAR sequence. The first pulse rotates spins into the $\hat{x}$-$\hat{y}$ plane where the spin polarization decays due to transverse spin relaxation in a time $T_2^* = 4\,\mu$s. For τ significantly longer than T_2^*, the final polarization vanishes so the signal will be half of the value observed for short τ.

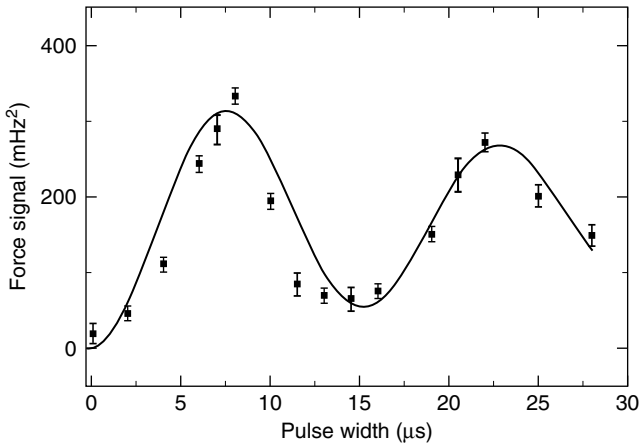

Figure 16. Nutation of the statistical polarization in CaF_2. (Reprinted with permission H J Mamin *et al*., copyright 2005, American Physical Society.) The signal is shown as a function of the pulse width t_p. The spin oscillation period about the effective field indicates an rf field strength $H_1 = 17$ Oe.

This demonstration of standard pulse techniques in combination with ultrasensitive NMR detection reinforces the expectation that MRFM detected NMR will be a powerful tool for microscopic studies of materials.

5.3.2 NMR double resonance in force microscopy

We have seen that MRFM allows NMR detection with the sensitivity much higher than that of the conventional NMR (2000 spins in the IBM experiment, (Mamin, Budakian, Chui and Rugar, 2005) compared to at least 10^{12}–10^{13}). To fully exploit this strength the conventional pulsed NMR techniques must be brought to bear. Important steps in this direction have been demonstrated by (Lin *et al*., 2006). Here we briefly describe their application of solid-state double resonance techniques in an MRFM experiment performed on ^{19}F and ^{31}P nuclei in a KPF_6 crystal.

A useful and commonly used solid-state NMR double resonance technique is Hartmann–Hahn cross polarization (CP) in which polarization transfer from a more easily polarized spin species (e.g., due to a higher gyromagnetic ratio) to a less polarized species provides increased detection sensitivity for the latter. The technique employs irradiation at two rf frequencies (ω_{L}^I and ω_{L}^{II}) with H_1 intensities chosen such that $\gamma^{\text{I}} H_1^{\text{I}} = \gamma^{\text{II}} H_1^{\text{II}}$.

The applicability of these techniques to MRFM detection in the presence of the gradient from a 0.5-mm iron wire has been explored in samples containing $\sim 10^{15}$ spins. Figure 17 shows the growth of the ^{31}P spin polarization as a function of the time τ_{cp} the cross polarization rf field is applied. The

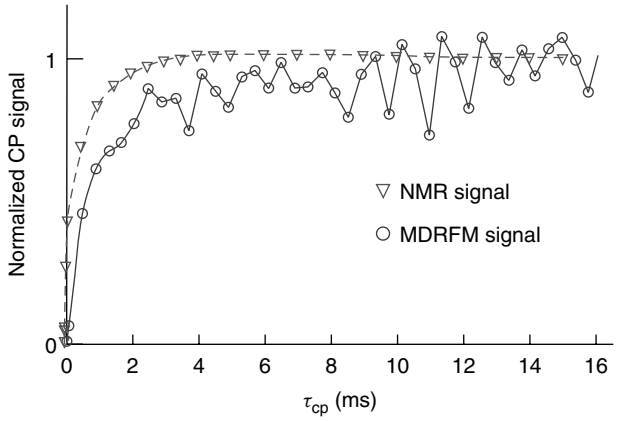

Figure 17. The buildup of the ^{31}P spin polarization as a function of τ_{cp} of the CP pulse sequence was measured using cyclic adiabatic inversion (○). Data acquired in a conventional NMR experiment on the same spin system (▽). (Reprinted with permission Q Lin *et al*., copyright 2006, American Physical Society.)

MRFM data are in good agreement with data acquired in a conventional NMR experiment.

Spin decoupling

Another application of double resonance is to narrow resonance lines in to enhance the resolution of solid-state NMR spectroscopy. A common broadening mechanism in solids results from the interaction between the target spin and neighboring dissimilar spins (heteronuclear coupling). This interaction can be reduced by irradiating at the Larmor frequency of the offending species to average the interaction to zero. During decoupling the target signal is detected at its Larmor frequency.

The Meier group has also demonstrated (Lin *et al*., 2006) narrowing of the ^{31}P line through continuous wave (CW) decoupling applied at the ^{19}F Larmor frequency. The ^{31}P linewidth was measured using a Hahn echo technique in which the echo amplitude is measured using cyclic adiabatic inversion to generate the MRFM signal (Degen *et al*., 2005). The Hahn echo alone will also reduce heteronuclear line broadening but CW decoupling is superior. The linewidth after the echo was 1.4 kHz, this was reduced to 900 Hz by decoupling.

The ability to use pulsed techniques to improve spectral resolution in MRFM is an important advance: when combined with high sensitivity MRFM detection it points toward the potential for local NMR spectroscopy with unprecedented spatial resolution.

5.3.3 1D NMR MRFM imaging of GaAs

The demonstration of NMR/MRFM imaging of Ga in GaAs by D. Smith and colleagues (Thurber, Harrell and Smith, 2003) indicates the promise MRFM holds for studies of microelectronic devices composed of important electronic semiconductors. For multicomponent devices the unique ability of MRFM to observe buried structures is a key strength.

Thurber and Smith *et al*. have obtained 1D NMR/MRFM images of a GaAs sample mounted on the cantilever. Even at $T = 5$ K in a 4 T applied magnetic field the nuclear spin polarization is small, so they optically pumped the electron spin polarization with circularly polarized light to enhance the nuclear polarization. Distinct NMR signals from three nuclear isotopes: (^{71}Ga, ^{69}Ga, and ^{75}As), were detected using cyclic adiabatic inversion. In addition, they obtained high resolution, 1D ^{71}Ga MRFM images from the GaAs sample whose nuclear spin polarization was controllably modified prior to imaging. The optically pumped nuclear magnetization was artificially suppressed by prolonged cyclic adiabatic inversion in two spatial regions separated by a volume of unperturbed magnetization. The MRFM signal was subsequently recorded as the sensitive slice was swept through the sample during the imaging cycle; this revealed the two regions of diminished magnetization at different values of the applied field as shown in Figure 18. The regions can still be resolved as their separation is reduced to 500 nm. The authors estimate their limiting 1D spatial resolution in the experiment to be 170 nm with detection sensitivity of $\sim 4 \times 10^{11}$ ^{71}Ga Hz$^{-1/2}$.

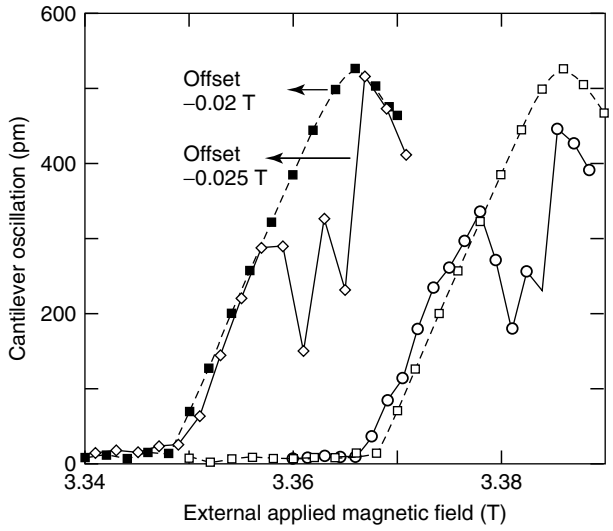

Figure 18. Demonstration of spatially resolved NMR in optically pumped ^{71}Ga. (Reprinted with permission K R Thurber *et al*., copyright 2003, Elsevier.) The spin polarization was suppressed in two closely spaced slices and then imaged for two slice separations: 670 nm (◇) and 500 nm (○). For comparison, spectra obtained from optically pumped sample with no slice saturation are shown (□ and ■). (The difference in offset between the unmodified (■, offset −0.02 T) and the 670 nm (◇, offset −0.025 T) data is believed to be caused by a slight change <1 μm in the separation between the sample and magnet for these data runs done on different days.

6 CONCLUSIONS

We have discussed the methods and techniques of MFRM, an emerging fully three-dimensional high-resolution scanned-probe technique. While focusing on detailed discussions of the experimental approaches used, we have also pointed out several successful applications. The rapid improvement in the capabilities of the technique culminating notably in the detection of individual electronic spins demonstrate that it is a robust and flexible technique. The range of successful applications serve to confirm this and indicate its broad potential.

ACKNOWLEDGMENTS

Tunneling Magnetoresistance in Semiconductors

Shinobu Ohya[1,2] and Masaaki Tanaka[1,2]

[1] *University of Tokyo, Tokyo, Japan*
[2] *Japan Science and Technology Agency, Saitama, Japan*

1 INTRODUCTION

Over the past few years, tunneling magnetoresistance (TMR) and related phenomena have been extensively studied in magnetic tunnel junctions (MTJs) composed of ferromagnetic semiconductors (FMSs), such as (In,Mn)As (Munekata *et al*., 1989; Ohno, Munekata, Molnar and Chang, 1991; Ohno *et al*., 1992) and (Ga,Mn)As (Ohno *et al*., 1996; Hayashi *et al*., 1997a; Van Esch *et al*., 1997). These FMS-based MTJs are fully epitaxial and single crystalline, and have atomically flat interfaces; thus reductions of leak current and roughness scattering are expected, leading to large TMR. Moreover, novel functions induced by quantum-size effects are expected in FMS-based quantum heterostructures.

Among these semiconductor-based MTJ structures, (Ga,Mn)As-based MTJs have been extensively studied, because (Ga,Mn)As is a ferromagnetic (FM) p-type semiconductor with a zinc blende–type crystal structure having almost the same lattice constant as GaAs and AlAs. Therefore, (Ga,Mn)As/(GaAs or AlAs) III–V-based heterostructures can be epitaxially grown with abrupt interfaces and with atomically controlled layer thicknesses (Hayashi *et al*., 1997b; Ohno, 1999; Ohno *et al*., 1999; Tanaka *et al*., 2000a,b). Several advantages are expected in MTJs of GaMnAs-based III–V heterostructures: (i) One can form high-quality single crystalline MTJs made of all-semiconductor heterostructures, which can be easily integrated with other III–V-based structures and devices. (ii) In principle, many parameters such as the barrier height, barrier thickness, and the Fermi energy of FM electrodes are controllable. (iii) Introduction of quantum heterostructures, such as double-barrier resonant tunneling diodes, is probably easier than any other material system. In Section 2, we mainly focus on the GaMnAs-based single-barrier MTJs. The basic characteristics of TMR and the theoretical understanding in these single-barrier structures are presented. In the last part of Section 2, recent progress of TMR studies in semiconductor-based single-barrier MTJs including other materials is reviewed.

Combining the quantum-size effect and TMR is one of the very important issues for adding novel functionalities to semiconductor-based spin-electronic devices. Recently, theoretical calculations and experiments of GaMnAs-based double-barrier MTJs have been carried out. The theoretical calculations predict that TMR is largely enhanced by the quantum-size effect. In Section 3, these theoretical predictions and experiments on GaMnAs-based double-barrier MTJs are reviewed.

In Section 4, recently observed novel phenomena, materials, and structures related to TMR in semiconductors are described. The first of them is the tunneling anisotropic magnetoresistance (TAMR), which was observed in GaMnAs-based heterostructures (Gould *et al*., 2004; Rüster *et al*., 2005). TAMR seems very similar to TMR, but the

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

characteristics differ considerably. Although the mechanism of TAMR has not been fully understood, experimental results and present understandings of TAMR are briefly mentioned in this section. Second, the recent observation of TMR in MnAs/AlAs/GaAs:MnAs MTJ structures, where the bottom electrode is composed of FM MnAs nanoclusters embedded in GaAs (we refer to as GaAs:MnAs), is presented (Hai, Yokoyama, Ohya and Tanaka, 2006). In this structure, TMR is induced by spin-polarized carriers moving through the MnAs nanoclusters. Because the T_C value of MnAs is above room temperature, it is expected that TMR devices operating at room temperature could be realized. Also, it was clarified that the bias voltage V_{half} at which the TMR ratio is reduced by half is surprisingly as high as 1200 mV, which is much higher than V_{half}($\sim$40 mV) of FMS-based MTJs. Here, the basic characteristics of GaAs:MnAs-based MTJs are introduced. Finally, application of TMR to three terminal devices is described. In the recently proposed spin transistors of metal-oxide-semiconductor (MOS) gate structure (spin MOSFET; Sugahara and Tanaka, 2004, 2005), spin injection from the FM source into the semiconductor channel via spin-polarized tunneling is essential for device operation. The device structure, operation principle, and applications of the spin MOSFET are reviewed.

2 TMR IN SINGLE-BARRIER MAGNETIC TUNNEL JUNCTIONS

2.1 Early studies of TMR in GaMnAs-based MTJs

The first observation of TMR in a GaMnAs-based heterostructure was reported by Hayashi, Shimada, Shimizu, and Tanaka (1999). TMR was observed in a fully epitaxial MTJ structure of $Ga_{0.961}Mn_{0.039}As$ (200 nm)/AlAs (3 nm)/$Ga_{0.961}Mn_{0.039}As$ (200 nm) grown by low-temperature molecular-beam epitaxy (LT-MBE). Figure 1 shows the TMR curve observed in GaMnAs/AlAs/GaMnAs MTJ with a magnetic field applied in plane along the [110] direction at 4.2 K. Because the lattice constant of GaMnAs is slightly larger than that of GaAs, the GaMnAs film grown on GaAs receives a compressive strain, having an in-plane magnetic anisotropy, so as to minimize the magnetostatic energy. Thus, hysteretic MR curves can be obtained when a magnetic field is applied along the in-plane direction of the GaMnAs film. In this study, the TMR ratio of around 5% was obtained at 4.2 K. Here, we define the TMR ratio as $(R_{AP} - R_0)/R_0$, where R_{AP} and R_0 are resistances in antiparallel magnetization and in parallel magnetization at zero magnetic field, respectively. (When the TMR ratio

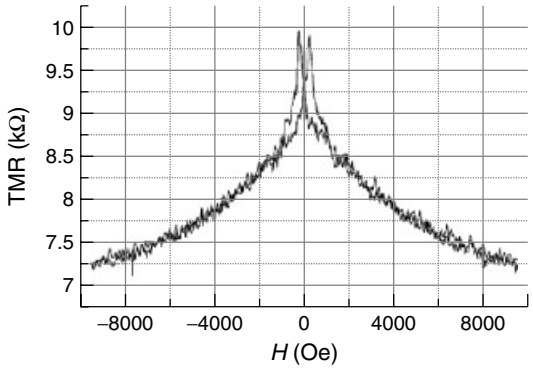

Figure 1. Magnetic-field dependence of tunneling resistance measured at 4.2 K on $Ga_{0.961}Mn_{0.039}As$ (200 nm)/AlAs (3 nm)/$Ga_{0.961}Mn_{0.039}As$ (200 nm). (Reproduced from Hayashi *et al*., 1999, with permission from Elsevier. © 1999.)

is defined as $(R_{max} - R_{min})/R_{min}$, where R_{max} and R_{min} are the maximum and minimum resistances respectively, in Figure 1, it is 36% at 4.2 K). After this experiment, in 2000, Chiba *et al*. observed TMR in a $Ga_{0.95}Mn_{0.05}As$/AlAs (3 nm)/$Ga_{0.97}Mn_{0.03}As$ MTJ (Chiba *et al*., 2000). They grew this structure on an InGaAs buffer layer whose lattice constant is larger than GaMnAs. In this case, the GaMnAs films receive a tensile strain, leading to an out-of-plane magnetic anisotropy. They applied magnetic field perpendicular to the film plane, and observed the TMR ratio of around 5.5% at 20 K.

2.2 Basic characteristics of TMR in GaMnAs-based MTJs

In 2001, a large TMR ratio (>70%, maximum 75%) was observed by Tanaka and Higo in GaMnAs/AlAs/GaMnAs MTJs at 8 K (Tanaka and Higo, 2001, 2002). This large increase of TMR was achieved by the improved quality of the GaMnAs layers and the tunnel barrier, and by optimization of the device structures. In the GaMnAs MTJ structures, it is known that there are many defects such as the As antisites (Grandidier *et al*., 2000) and the Mn interstitials (Yu *et al*., 2002), whose concentration strongly depends on the MBE growth conditions. Thus, controlling these defects is important for fabricating the GaMnAs MTJ structures. In this study, systematic investigations, such as AlAs barrier-thickness dependence, temperature dependence, and magnetic-field-direction dependence of TMR, were carried out. Here, these basic characteristics of TMR in GaMnAs-based single-barrier MTJs are reviewed.

Figure 2 illustrates the sample structure and preparation process, using LT-MBE and patterning by photolithography. After a 100-nm-thick Be-doped GaAs buffer layer was grown at 580 °C on a p^+-GaAs(001) substrate, a $Ga_{1-x}Mn_xAs$

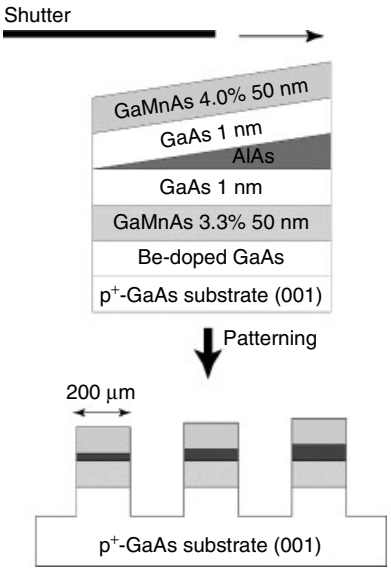

Figure 2. Preparation of a wedge-type ferromagnetic semiconductor trilayer heterostructure by LT-MBE and mesa-etched round-shaped MTJs, 200 μm in diameter. (Reproduced from Tanaka *et al*., 2001, with permission from the American Physical Society. © 2001.)

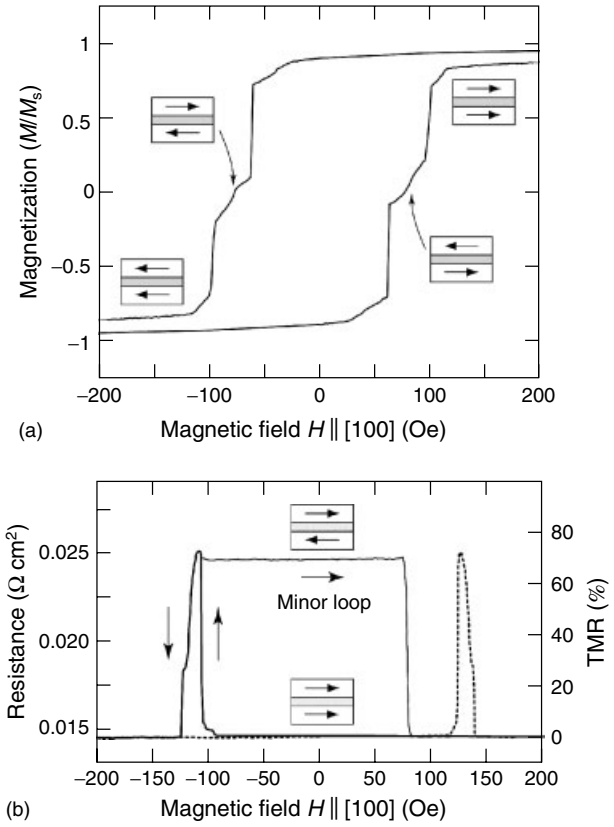

Figure 3. (a) Magnetization of a $Ga_{1-x}Mn_xAs$ ($x = 4.0\%, 50\,nm$)/AlAs (3 nm)/$Ga_{1-x}Mn_xAs$ ($x = 3.3\%, 50\,nm$) trilayer measured by SQUID at 8 K. The specimen size was $3 \times 3\,mm^2$. The vertical axis shows the normalized magnetization M/M_s, where M_s is the saturation magnetization. (b) TMR curves at 8 K of a $Ga_{1-x}Mn_xAs$ ($x = 4.0\%, 50\,nm$)/AlAs (1.6 nm)/$Ga_{1-x}Mn_xAs$ ($x = 3.3\%, 50\,nm$) tunnel junction. The tunnel junctions were mesa-etched diodes 200 μm in diameter. Bold solid and dashed curves are major loops, with the magnetic-field sweep direction from positive to negative and negative to positive, respectively. A minor loop is shown by a thin solid curve. In both (a) and (b), the magnetic field was applied along the [100] axis in the plane. (Reproduced from Tanaka *et al*., 2001, with permission from the American Physical Society. © 2001.)

($x = 4.0\%, 50\,nm$)/AlAs (d_{AlAs})/$Ga_{1-x}Mn_xAs$ ($x = 3.3\%$, 50 nm) trilayer was grown at 250°C. By using a shutter moving linearly in front of the substrate, the barrier thickness d_{AlAs} was changed from 1.3 to 2.8 nm within a wafer of $20 \times 20\,mm^2$. The slope of the wedge was estimated by the growth rate of AlAs, which was obtained by reflection high-energy electron diffraction (RHEED) oscillations and the moving speed of the shutter. Preparation of wedge-type samples is important in order to characterize the dependence of the TMR of MTJs on the barrier thickness, because the electronic and magnetic properties of the GaMnAs layers are very sensitive to the growth conditions (Shimizu, Hayashi, Nishinaga and Tanaka, 1999). In addition, undoped 1-nm-thick GaAs spacers were inserted between GaMnAs and AlAs to make the interfaces smooth and to avoid Mn diffusion into the barrier, which may cause spin-flip scattering. In order to measure the tunneling transport, the sample was patterned by photolithography and mesa etching, into arrays of round-shaped mesa junctions, 200 μm in diameter with various barrier thicknesses ranging from 1.3 nm to 2.8 nm.

2.2.1 *Experimental results of TMR in the GaMnAs/AlAs/GaMnAs MTJs*

The magnetization of the $Ga_{1-x}Mn_xAs$ ($x = 4.0\%, 50\,nm$)/AlAs (3 nm)/$Ga_{1-x}Mn_xAs$ ($x = 3.3\%, 50\,nm$) trilayer measured by superconducting quantum interference device (SQUID) at 8 K is shown in Figure 3(a). In the SQUID measurements, the trilayer sample was cleaved into a square shape with an area of $3 \times 3\,mm^2$. The magnetic field was applied along the [100] axis in the plane. Pairs of arrows in the figure indicate the magnetization directions of the top and bottom GaMnAs layers at different fields. Owing to the different coercivity of the two GaMnAs layers, a double-step magnetization curve with coercive fields of about 60 and 100 Oe was observed. The easy magnetization axis of the FM GaMnAs layers lies in the film plane.

Figure 3(b) shows tunnel resistance versus magnetic field, that is, TMR curves measured at 8 K on a junction with $d_{AlAs} = 1.6\,nm$ when the magnetic field was applied along the [100] axis in the plane. The measurements were done at

a constant bias of 1 mV, and so there is no hot carrier effect. Bold solid and dashed curves (major loops) in Figure 3(b) were obtained by sweeping the field from positive to negative and negative to positive, respectively. As shown by the bold solid curve, when the magnetic field H was swept from the positive saturation field down to negative, the tunnel resistance $R(H)$ increased from 0.014 to 0.025 $\Omega\,\mathrm{cm}^2$ (corresponding TMR was 72%) at $H = -110$ Oe, where the magnetization of one GaMnAs layer reversed and the magnetization configuration changed from parallel to antiparallel. Sweeping the field further to the negative direction, $R(H)$ and TMR decreased to their initial values ($R(H) = 0.014\,\Omega\,\mathrm{cm}^2$) at $H = -125$ Oe, where the magnetization of the other GaMnAs layer reversed and the magnetization configuration became parallel again. The difference of the coercive fields between the M–H curve in Figure 3(a) and the TMR curve in Figure 3(b) is caused by the difference in the shape and size of the measured specimens. Note that the TMR value is over 70%, much higher than the TMR previously reported. A thin solid curve in Figure 3(b) shows a minor loop, indicating that the antiparallel magnetization configuration is stable, as well as the parallel magnetization configuration. The switching fields of the major and minor loops are different. This is a general feature of the coercivity in GaMnAs films and it depends on the maximum magnetic field applied just before the switching. This is probably related to the domain wall pinning, whose unpinning energy depends on the maximum magnetic field applied just before the switching of magnetization. In this case, the minor loop is measured with the maximum magnetic field of -120 Oe, while the major loops are measured with the maximum magnetic fields of ± 1 T. Therefore, the switching field of the minor loop is smaller than that of the major loop.

Figure 4(a) shows the tunnel resistance R for the tunnel junctions measured at 8 K as a function of the barrier thickness d_{AlAs}. The resistance exponentially increased over a wide range from 10^{-3} to $10\,\Omega\,\mathrm{cm}^2$ as d_{AlAs} increased, which means that high-quality tunnel junctions were formed with a constant barrier height. In the WKB approximation, the slope of ln R–d_{AlAs} characteristics is given by $2[2m^* V_{\mathrm{b}}]^{1/2}/\hbar$, thereby estimating the product $m^* V_{\mathrm{b}}$ to be $0.32 m_0$ kg·eV, where m_0 is the free-electron mass, m^* is the effective mass of holes, and V_{b} is the barrier height. The valence band offset between GaMnAs and AlAs is unknown but it is considered to be close to that ($\sim$0.55 eV) of GaAs and AlAs, and the Fermi energy of holes in GaMnAs is 0.1 to 0.2 eV, thus the barrier height V_{b} is $\sim$0.45 eV. Therefore, the effective mass m^* of holes that are responsible for tunneling is roughly estimated to be $\sim 0.7 m_0$.

Figure 4(b) shows barrier-thickness dependence of TMR at 8 K when the magnetic field was applied in plane along the [100] and [1$\bar{1}$0] axes. The maximum TMR was 75%

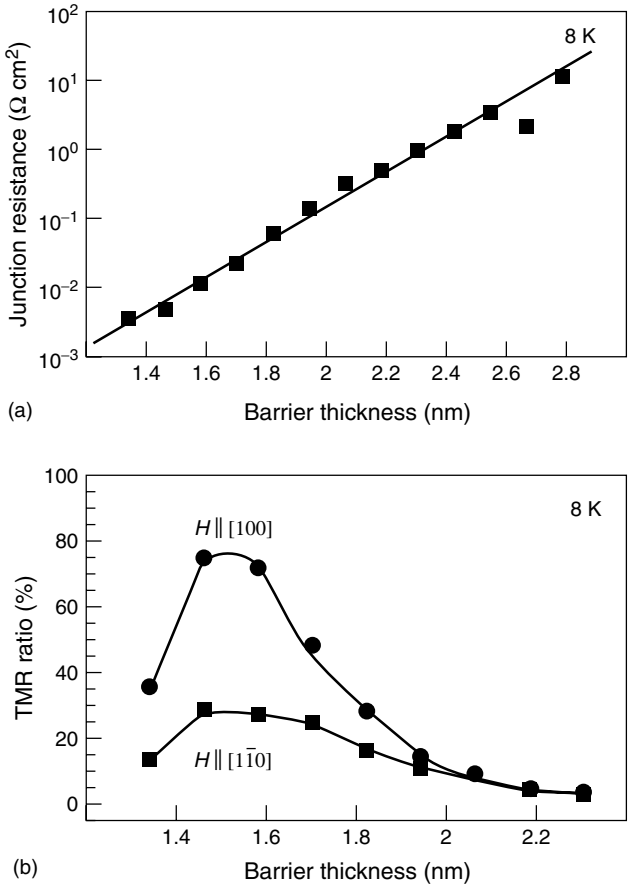

Figure 4. Barrier-thickness dependence of (a) the tunnel resistance and (b) the TMR in $Ga_{1-x}Mn_xAs$ ($x = 4.0\%$, 50 nm)/AlAs (d_{AlAs})/$Ga_{1-x}Mn_xAs$ ($x = 3.3\%$, 50 nm) tunnel junctions measured at 8 K. In (b), the TMR values were measured with the magnetic field applied along the [100] and [1$\bar{1}$0] axes. (Reproduced from Tanaka *et al.*, 2001, with permission from the American Physical Society. © 2001.)

at $d_{\mathrm{AlAs}} = 1.46$ nm when the field was applied along the [100] axis. In both field directions, with increasing d_{AlAs} (>1.5 nm), the TMR was found to rapidly decrease. At all the values of d_{AlAs}, the TMR was higher when the field was applied along the [100] axis than along the [1$\bar{1}$0] axis. The difference of the TMR between the two directions of the field is due to the cubic magnetocrystalline anisotropy induced by the zinc blende–type GaMnAs crystal structure, where the easy magnetization axis of GaMnAs is ⟨100⟩, the details of which is reported in the literature (Higo, Shimizu and Tanaka, 2001). Although the reason for the drop in the TMR for the junction with $d_{\mathrm{AlAs}} < 1.4$ nm is not clear at present, this drop could be caused by the decrease of the effective barrier height because of the interface roughness or the image potential. Another possible reason is the FM interlayer exchange coupling between GaMnAs layers separated by a very thin AlAs layer.

When TMR was measured on many round-shaped mesa tunnel junctions, a variety of different characteristics were observed, as shown in Figure 5(a)–(d). Here, the magnetic field was applied in plane along the [100] axis. Because the present tunnel junctions are totally monocrystalline and GaMnAs is considered to have the magnetocrystalline anisotropy with the easy magnetization axis of ⟨100⟩, the magnetization direction of the top and bottom GaMnAs layers favors to be along one of the four easy axes ([100], [010], [$\bar{1}$00], [0$\bar{1}$0]) in the film plane. These TMR behaviors are attributed to the different magnetization configurations, as illustrated in the lower panel of Figure 5. Here, solid and gray arrows are the magnetization directions of the two GaMnAs layers, and time evolutions of magnetization configuration are depicted when the applied magnetic field is changed from positive (+200 Oe) to negative (−200 Oe). These TMR behaviors are well explained by the analysis of magnetization rotation based on the single domain theory. The multivalue characteristics of TMR owing to the magnetocrystalline anisotropy could lead to interesting applications such as multivalue recording and novel logic circuitry.

Temperature dependence of the TMR for these various junctions with different d_{AlAs} are measured and the normalized conductance difference data $\Delta G = \Delta G(T)/\Delta G$ (8 K) are plotted in Figure 6, where T is temperature, $\Delta G(T) = G_{\mathrm{P}}(T) - G_{\mathrm{AP}}(T)$, $G_{\mathrm{P}}(T)$ and $G_{\mathrm{AP}}(T)$ are the

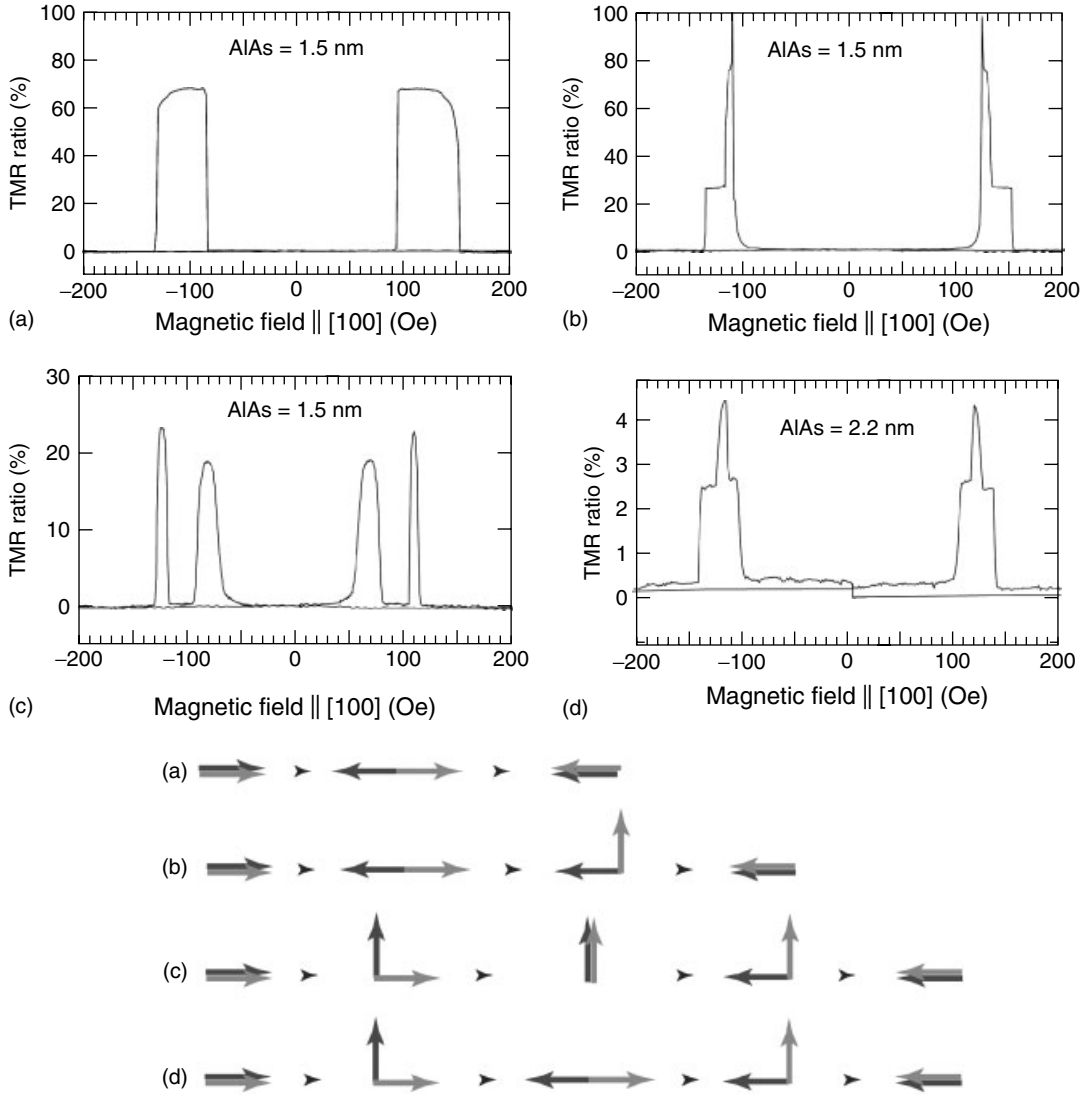

Figure 5. A variety of TMR characteristics of round-shaped mesa tunnel junctions at 8 K. The magnetic field was applied in plane along the [100] axis. In the lower panel, time evolutions of magnetization configuration are depicted when the applied magnetic field is changed from positive (+200 Oe) to negative (−200 Oe). Solid and gray arrows are the magnetization directions of the two GaMnAs layers. (Reproduced from Tanaka *et al*., 2002, with permission from Elsevier. © 2002.)

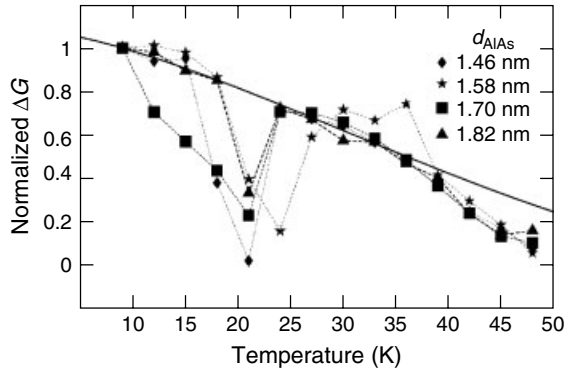

Figure 6. Temperature dependence of the normalized conductance difference ΔG (equivalently TMR) for various junctions with different $d_{\mathrm{AlAs}} = 1.46, 1.58, 1.70, 1.82$ nm. The solid line is the fit to the theory based on thermal spin-wave excitations (Tanaka and Higo, 2001, 2002). (Reproduced from M. Tanaka *et al*., 2002, with permission from Elsevier. © 2002.)

junction conductances at T K for parallel and antiparallel magnetization, respectively. ΔG (equivalently, TMR) basically decreased with increasing temperature and vanished at ∼50 K, which is the Curie temperature of one of the GaMnAs layers. ΔG dropped once at ∼20 K, because the coercivity of the top and bottom GaMnAs layers is so close (almost same) that the window for antiparallel magnetization is too small, which was confirmed by temperature-dependent magnetization measurements, thus ΔG was difficult to be observed at around 20 K. A solid line in Figure 6 is the fit to the theory $\Delta G(T) = \Delta G_0(1 - \alpha T^{3/2})^2$, where ΔG_0 is a constant and α is fitted to $1.5 \times 10^{-3}\,\mathrm{K}^{-3/2}$, based on thermal spin-wave excitations (Shang, Nowak, Jansen and Moodera, 1998). The theory can explain the present data, as it did for conventional $Co/Al_2O_3/Co(NiFe)$ MTJs. This means that the dominant contribution to the tunnel conductance is direct elastic tunneling with the tunneling carrier spin polarization P decreasing as $1 - \alpha T^{3/2}$. Both the excellent scaling of the junction resistance with the AlAs barrier thickness (Figure 4a) mentioned earlier and this temperature dependence of ΔG give strong evidence for TMR junctions.

2.2.2 *Tight binding calculations of TMR*

In the conventional Jullière's model (Jullière, 1975), the TMR depends only on the spin-dependent density of states (DOSs) in the two FM electrodes and does not depend on the barrier thickness d, and hence the Jullière model cannot explain these experimental results. Because the present GaMnAs/AlAs/GaMnAs heterostructures are epitaxially grown single crystals, the wave vector $\boldsymbol{k}_\parallel$ of carriers parallel to the interface should be conserved in tunneling. Calculations using the tight binding theory including $\boldsymbol{k}_\parallel$ conservation by Mathon (1997) is consistent with the experimental results of barrier-thickness dependence of TMR mentioned earlier.

The experimental results can be qualitatively explained as follows: Figure 7 shows the Fermi surfaces for up and down spins in two FM electrodes, calculated by the single orbital, tight binding model, when the magnetization configuration is (a) parallel and (b) antiparallel. Also, the dispersion of the decaying factor κ_z in the barrier layer was calculated and shown in the middle of the figure. The wave vector $k_z(E_F, \boldsymbol{k}_\parallel)$ normal to the interface in the FM electrodes is determined from $E_F = E_0 + 2t\cos(k_z a) + w(\boldsymbol{k}_\parallel)$, and the decaying factor $\kappa_z(E_F, \boldsymbol{k}_\parallel)$ in the barrier layer is determined from $E_F = E_0 + 2t\cosh(\kappa_z a) + w(\boldsymbol{k}_\parallel)$, where $w(\boldsymbol{k}_\parallel) = 2t[\cos(k_x a) + \cos(k_y a)]$, $\boldsymbol{k}_\parallel = (k_x, k_y)$ is the wave vector parallel to the film plane, E_F is the Fermi energy, E_0 is the on-site energy in each layer, t is the nearest-neighbor hopping parameter, and a is the lattice constant (Mathon, 1997). The spin polarization in the FM electrodes was regarded as the difference of E_0 between the majority and minority carriers. When the magnetizations of the two FM electrodes are parallel as shown in Figure 7(a), the majority (minority) spin is the up (down) spin in both electrodes, so that the carriers can tunnel through all the channels $(\boldsymbol{k}_\parallel, \sigma)$. When the magnetizations of the two FM electrodes are antiparallel as shown in Figure 7(b), the down spin is the majority spin in the right electrode, thus the carriers with $k_\parallel = |\boldsymbol{k}_\parallel| > k_{\mathrm{cutoff}}$ cannot tunnel, where k_{cutoff} is the cutoff wave vector which is the largest $k_\parallel$ in the minority spin band. This difference of tunneling between parallel and antiparallel configurations indicates that the TMR is mainly caused by carriers with large $k_\parallel (> k_{\mathrm{cutoff}})$. However, these carriers with larger $k_\parallel$ exponentially decay more rapidly during tunneling in the barrier because of larger κ_z, as shown in the middle of Figure 7. Because of this in-plane dispersion of $\kappa_z(\boldsymbol{k}_\parallel)$, when the barrier thickness d is large, the tunneling conductance is dominated by the carriers with smaller $k_\parallel$, which do not contribute much to the TMR. Therefore, the TMR decreases as d increases.

In order to compare with the experimental TMR obtained in the GaMnAs/AlAs/GaMnAs tunnel junctions, the dependence of TMR on d_{AlAs} was calculated using the spin-orbit nearest-neighbor sp^3s^* model (Vogl, Hjalmarson and Dow, 1983; Chadi, 1977). The tight binding parameters reported by Schulman and Chang were used to obtain the realistic band structures of GaAs and AlAs (Schulman and Chang, 1985). The effect of Mn ions in GaMnAs was simplified by introducing an additional term ΔJ_x into the intralayer coupling matrices in the sp^3s^* Hamiltonian. Here J_x is a 10×10 matrix derived from the x component of the total angular momentum $\boldsymbol{J}$ in the planar-orbital basis. J_x was used because the magnetization was along the [100] axis. This additional

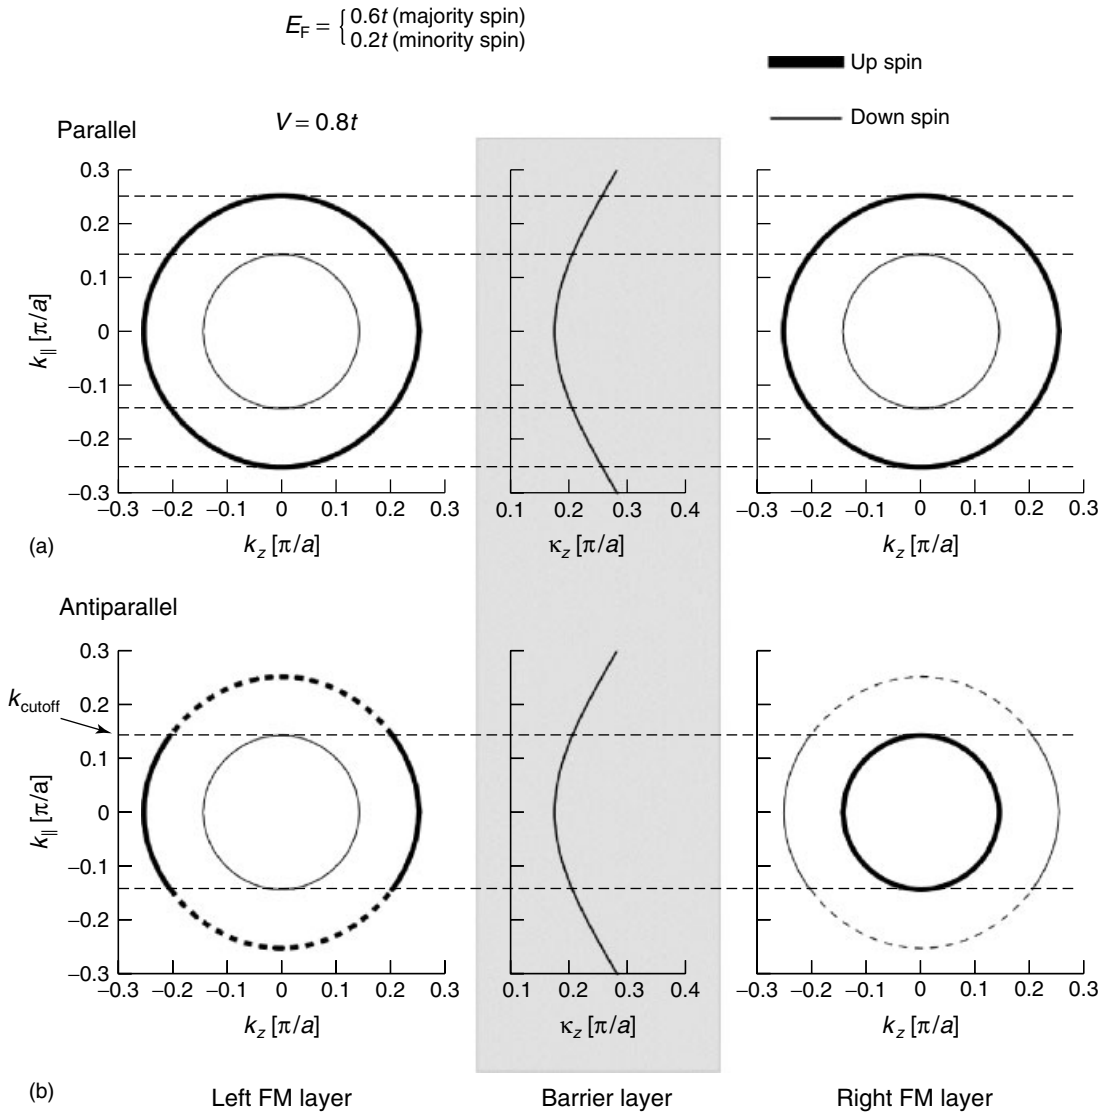

Figure 7. Fermi surfaces of the simple cubic lattice calculated by the single orbital tight binding model for up and down spins with the spontaneous spin splitting in (a) parallel and (b) antiparallel magnetization configurations. Dependence of the decaying factor κ_z in the barrier on $\mathbf{k}_\parallel$ is also shown in the middle of the Figure. (Reproduced from Tanaka *et al.*, 2001, with permission from the American Physical Society. © 2001.)

term causes the changes of the on-site energies proportional to J_x. The scalar proportional coefficient Δ corresponds to the spin-splitting energy between the two holes $|3/2, 1/2>$ and $|3/2, -1/2>$ at the Γ point.

In order to calculate TMR, tunneling probability T was first calculated, as shown in Figure 8, and plotted in the $\boldsymbol{k}_\parallel$ plane ($-0.3\pi/a < k_x < 0.3\pi/a$, $-0.3\pi/a < k_y < 0.3\pi/a$), both for parallel and antiparallel magnetization. The $\boldsymbol{k}_\parallel$ dependence of T is complex because of the complexity of the valence band structure of GaMnAs and AlAs. The band parameters used here are shown in the inset of Figure 9. Despite the complexity, the essential point is as follows. When the AlAs barrier thickness is as thin as 1 monolayer (ML), T has some nonzero values even at large $k_\parallel$ for parallel magnetization, whereas T is zero at large $k_\parallel$ for antiparallel magnetization. This difference in T between parallel and antiparallel magnetization leads to large TMR. In contrast, when the AlAs barrier thickness is greater (5 MLs), T is significantly suppressed at large $k_\parallel$ for parallel magnetization due to large κ_z, as described above, thus the difference in T between parallel and antiparallel magnetization is smaller, resulting in smaller TMR.

Figure 9 shows the calculated (solid curve) and measured (solid circles) barrier-thickness dependences of the TMR in the present GaMnAs/AlAs/GaMnAs tunnel junctions. We assumed that E_F, V, and Δ were 0.2, 0.67, and 0.08 eV,

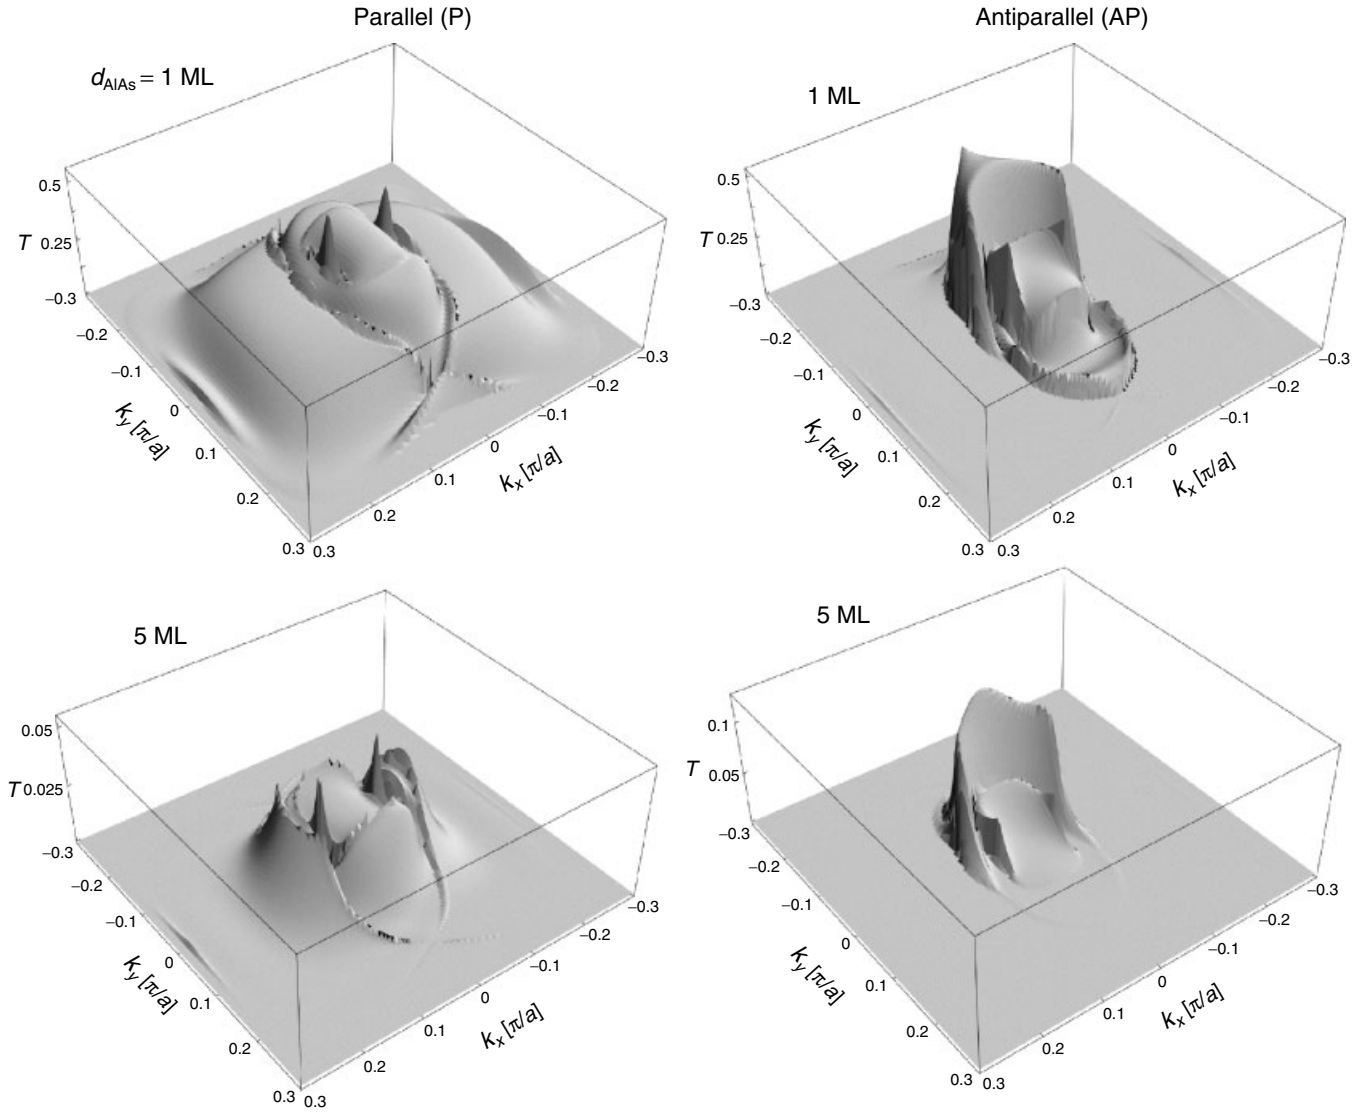

Figure 8. Tunneling probability T in GaMnAs/AlAs (d_{AlAs})/GaMnAs tunnel junctions plotted in the $\boldsymbol{k}_{\parallel}$ plane ($-0.3\pi/a \leq k_x \leq 0.3\pi/a$, $-0.3\pi/a \leq k_y \leq 0.3\pi/a$), both for parallel and antiparallel magnetization configurations, when the AlAs barrier thickness $d_{AlAs} = 1$ ML and 5 ML. (Reproduced from M. Tanaka *et al*., 2002, with permission from Elsevier. © 2002.)

respectively. The Fermi energy E_F and the valence band offset V were measured from the top of the valence band in the calculated GaMnAs band structure, as shown in the inset of Figure 9. $V = 0.67$ eV gives the valence band offset of 0.55 eV when $\Delta = 0$, that is, the case for normal GaAs/AlAs interfaces, which is a reasonable value. Compared with the experimental results, the calculated TMR decreases rapidly in the thinner barrier region. The barrier thickness was evaluated from RHEED oscillations and the moving speed of the shutter, as mentioned before. Because completely accurate alignment of the moving shutter with the substrate in the MBE chamber is difficult, the absolute values of the estimated barrier thickness may not be reliable (though the relative values are reliable), hence the calculated dependence was horizontally shifted towards right by 0.7 nm (only 2.5 ML) to fit to the experimental results, as shown by a dashed curve in Figure 9. The fitting is fairly good, but not perfect partly because the band structure of GaMnAs is not fully known yet, the model is simple compared with the more complex band structure, and/or partly because there could be spin scattering at the interfaces or in the tunnel barrier which is not taken into account. However, the present spin-orbit nearest-neighbor sp^3s^* model is found to explain the most essential part of the experimental barrier-thickness dependence of the TMR. Note that there are three essential points in this model. (i) The cutoff wave vector

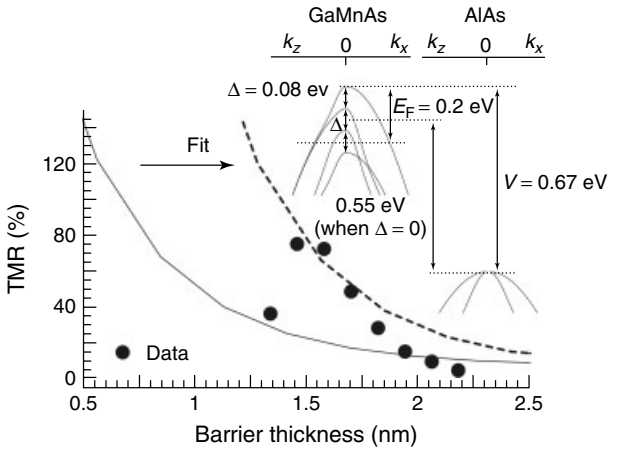

Figure 9. Solid curve represents the calculated dependence of TMR on the barrier thickness d_{AlAs} when the Fermi energy $E_{\mathrm{F}} = 0.2\,\mathrm{eV}$, the band offset $V = 0.67\,\mathrm{eV}$ (both measured from the top of the valence band of GaMnAs), and the spin splitting $\Delta = 0.08\,\mathrm{eV}$ between the two light holes $|3/2, 1/2\rangle$ and $|3/2, -1/2\rangle$ at the Γ point. Inset shows the band dispersion and the relationship of these parameters. The solid curve is horizontally shifted to the dashed curve by 0.7 nm (only 2.5 ML) to fit to the experimental results (solid circles, the magnetic field was along the [100] axis), because the absolute barrier thicknesses of the junctions are nominal. (Reproduced from Tanaka *et al*., 2001, with permission from the American Physical Society. © 2001.)

k_{cutoff} in the plane exists in the antiparallel configuration. (ii) The decaying factor κ_z in the barrier increases with increasing $k_{\parallel}$. (iii) $\boldsymbol{k}_{\parallel}$ is conserved in tunneling. Although these points may not be valid in the conventional MTJs with polycrystalline metallic electrodes, they are valid in the present $Ga_{1-x}Mn_xAs/AlAs/Ga_{1-x}Mn_xAs$ tunnel junctions, which are epitaxially grown single crystals.

2.3 More recent works on single-barrier MTJ

Recently, many materials have been used in the studies of semiconductor-based single-barrier MTJs, and furthermore the TMR ratio is increasing. Chiba *et al*. used GaAs as a tunneling barrier of the GaMnAs-based MTJ (Chiba, Matsukura and Ohno, 2004). They fabricated a $Ga_{0.926}Mn_{0.074}As$ (20 nm)/GaAs (6 nm)/$Ga_{0.956}Mn_{0.044}As$ (20 nm) MTJ, and observed high TMR ratios of 90% at 15 K, 105% at 4.7 K, and 290% at a very low temperature of 0.39 K with a magnetic field applied in plane along [100]. They also realized current-driven magnetization reversal in the GaMnAs (80 nm)/GaAs (6 nm)/GaMnAs (15 nm) MTJs (Chiba *et al*., 2004). The critical current densities, which are necessary to change parallel magnetization to antiparallel magnetization and *vice versa*, were $j_{\mathrm{AP}} = 1.92 \times 10^5\,\mathrm{A\,cm^{-2}}$ and $j_{\mathrm{P}} = 1.4 \times 10^5\,\mathrm{A\,cm^{-2}}$ at 30 K, respectively. These values are two orders of magnitude smaller than those observed in metal systems, resulting from the smaller magnetization of GaMnAs. For the current-driven magnetization reversal, a lower energy barrier is more appropriate. Elsen *et al*. fabricated a GaMnAs-based MTJ with a 6-nm-thick $In_{0.25}Ga_{0.75}As$ barrier, and realized current-driven magnetization reversal with smaller current densities of $j_{\mathrm{AP}} = 1.23 \times 10^5\,\mathrm{A\,cm^{-2}}$ and $j_{\mathrm{P}} = 1.37 \times 10^5\,\mathrm{A\,cm^{-2}}$ at 3 K ($j_{\mathrm{AP}} = 9.39 \times 10^4\,\mathrm{A\,cm^{-2}}$ and $j_{\mathrm{P}} = 9.86 \times 10^4\,\mathrm{Acm^{-2}}$ at 30 K) (Elsen *et al*., 2006). In the structure, also, a high TMR ratio of 155% was observed at 3 K.

Chun *et al*. used a FM metal of MnAs as a top electrode in order to investigate the spin injection from a metal to a semiconductor (Chun *et al*., 2002). They fabricated MnAs(45 nm)/GaAs(1 nm)/AlAs(d = 1, 2, 5, 10 nm)/GaAs (1 nm)/$Ga_{0.97}Mn_{0.03}As$(120 nm) MTJ structures, and obtained a TMR ratio of around 30% at 4.2 K when d is 5 nm.

Saito *et al*. used wide-gap (2.8 eV) II–VI semiconductor ZnSe as a barrier of the GaMnAs MTJ structure (Saito, Yuasa and Ando, 2005). The lattice constant of ZnSe (0.5669 nm) is very close to that of GaAs (0.5654 nm), and its optimum growth condition is comparable to that of GaMnAs (∼250 °C). These structural properties make it possible to grow epitaxial ZnSe/GaMnAs heterostructures. They fabricated a $Ga_{0.928}Mn_{0.072}As$ (50 nm)/ZnSe (1 nm)/$Ga_{0.928}Mn_{0.072}As$ (50 nm) MTJ structure, observing a TMR ratio of around 100% at 2 K. This result is expected to open a new possibility of realizing II–VI/III–V spin devices.

As mentioned earlier, large TMR ratios were obtained in GaMnAs-based MTJs, therefore GaMnAs is an excellent model material for realizing spin-electronic devices. For device application, however, there is a problem of low Curie temperature (T_{C}) of GaMnAs. When the FM transition of GaMnAs was first observed, T_{C} was only around 60 K (Ohno *et al*., 1996; Hayashi *et al*., 1997a). After that, the T_{C} value of GaMnAs was increased year after year and has reached 173 K in GaMnAs alloy films (Wang *et al*., 2005) and 250 K in the Mn δ-doped GaAs heterostructures (Nazmul *et al*., 2005). However, it is still lower than room temperature. On the other hand, the fabrication of new FMSs with T_{C} higher than room temperature has also been reported. $TiCoO_2$ is one of the recently developed FSs whose T_{C} is above 400 K (Matsumoto *et al*., 2001a,b). Toyosaki *et al*. used $TiCoO_2$ as a bottom electrode of MTJ (Toyosaki *et al*., 2005). They fabricated a $Fe_{0.1}Co_{0.9}/AlO_x/TiCoO_2$ MTJ, and observed a TMR ratio of ∼11% at 15 K. TMR was observed up to 180 K, but it disappeared above 180 K, which is much lower than T_{C} of $TiCoO_2$ (∼400 K). They pointed out that this was the result of inelastic tunneling in the amorphous barrier layer or the junction interface. If an epitaxial tunnel barrier can be grown on the $TiCoO_2$ bottom layer with high-quality interfaces, it is expected that the operating temperature of TMR can be improved.

3 DOUBLE-BARRIER MTJs

3.1 Theoretical predictions of the TMR behavior in GaMnAs-based resonant tunneling diodes

Combining spin-dependent tunneling and quantum-size effect is one of the very important issues for future semiconductor-based spintronic devices. By combining these effects, a large TMR enhancement and novel functions are expected to be realized, hence, theoretical calculations on the TMR behavior in GaMnAs-based resonant tunneling diodes (RTDs) have been carried out.

Hayashi *et al*. calculated the transmission probability of an RTD structure composed of GaMnAs/AlAs (28 Å)/GaMnAs (80 Å)/AlAs (28 Å)/GaMnAs, using a transfer matrix formalism (Hayashi, Tanaka and Asamitsu, 2000). They assumed a valence band profile along the direction perpendicular to the material interfaces shown in Figure 10(a). In this model, the magnetization directions of both GaMnAs electrodes are parallel to one another, and only the magnetization direction of the GaMnAs FM quantum well (angle θ, as shown in Figure 10(a) is changeable relative to the magnetization directions of the electrodes, because the coercive force of thin GaMnAs films is larger than that of thick GaMnAs films. Figure 10(b) and (c) show the calculated results of the energy dependence of the transmission probability ($TT^*(E_z)$) from one majority spin band to the other majority spin band. Figure 10(b) and (c) correspond to heavy holes ($m_{hh} = 0.45m_0$) and light holes ($m_{lh} = 0.08m_0$), respectively. The peak energies shift in both cases, depending on the magnetization direction of the FM quantum well. This result indicates that a FM quantum well works as a very sharp spin filter as well as an energy filter, leading to the enhancement and unique bias dependence of TMR.

Petukhov *et al*. calculated the TMR behavior in GaMnAs/AlAs/GaAs/AlAs/GaMnAs RTD structures comprising a nonmagnetic quantum well between two insulating AlAs barriers (Petukhov, Chantis and Demchenko, 2002). In the calculation, they used a multiband transfer matrix method with a Luttinger–Kohn and an exchange mean-field Hamiltonian (Dietl, Ohno and Matsukura, 2001). They predicted that a large TMR enhancement occurs even with such a nonmagnetic GaAs quantum well. This mechanism is depicted in Figure 11, and is explained as follows: (a) and (b) show the majority and minority spin bands in parallel magnetization, respectively; (c) and (d) show those in antiparallel magnetization, respectively. In this model, the resonant level E_R is assumed to exist between the bottoms of valence up-spin and down-spin bands. In parallel magnetization, the up-spin carriers can go through the RTD structure. In antiparallel magnetization, however, no carrier can go through, thus the

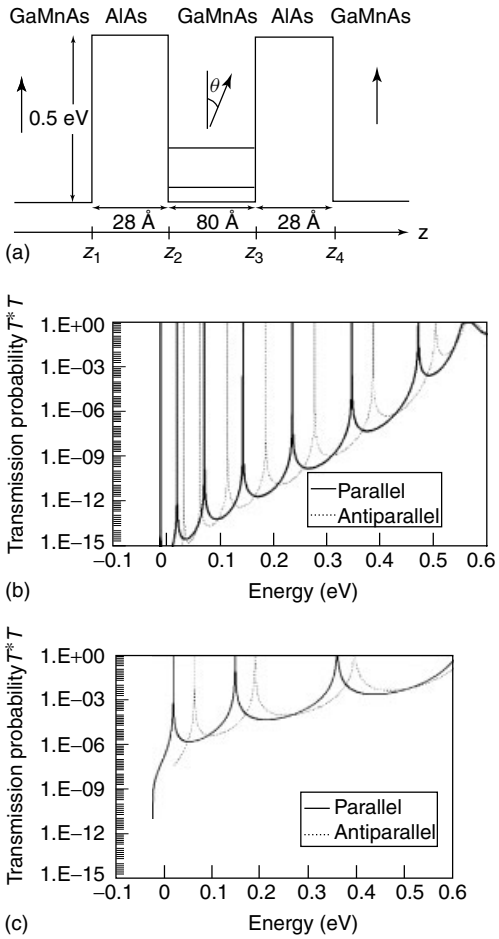

Figure 10. (a) Valence band profile of the GaMnAs-based double-barrier heterostructure. (b) Transmission probability for heavy holes ($m_{hh} = 0.45m_0$ for GaMnAs and $0.75m_0$ for AlAs, respectively). (c) Transmission probability for light holes ($m_{lh} = 0.08m_0$ for GaMnAs and $0.143m_0$ for AlAs, respectively). (Reproduced from Hayashi *et al*., 2000, with permission from the American Physical Society. © 2000.)

TMR ratio becomes very large. Figure 12 shows the calculated TMR ratio as a function of the thickness of the GaAs quantum well when the AlAs thickness w is 1, 1.5, and 2 nm. The inset is the schematic valence band diagram of these RTD structures. At a specific quantum well width, the TMR ratio is enhanced to 800% when the AlAs thickness is 2 nm.

3.2 Experimental studies on TMR in GaMnAs-based double-barrier MTJ structures

In order to observe the quantum-size effect in the GaMnAs-based RTD, Hayashi *et al*. fabricated a $Ga_{0.955}Mn_{0.045}As$/AlAs (2.8 nm)/$Ga_{0.965}Mn_{0.035}As$(8 nm)/AlAs (2.8 nm)/$Ga_{0.955}Mn_{0.045}As$ RTD structure on a p^+-GaAs(001) substrate, and

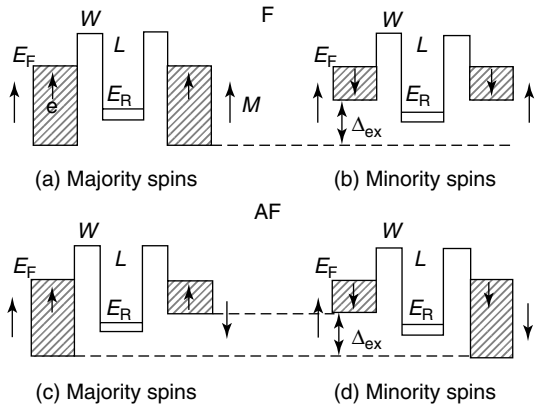

Figure 11. Band alignments of GaMnAs/AlAs/GaAs/AlAs/GaMnAs assumed by Petukhov *et al*. (a) and (b) The majority (up spin) and minority spin (down spin) bands in parallel magnetization, respectively; and (c) and (d) are those in antiparallel magnetization. Here, W, L, E_R, and Δ_{ex} are the AlAs thickness, the GaAs quantum well width, the resonant level, and the exchange energy, respectively. (Reproduced from Petukhov *et al*., 2002, with permission from the American Physical Society. © 2002.)

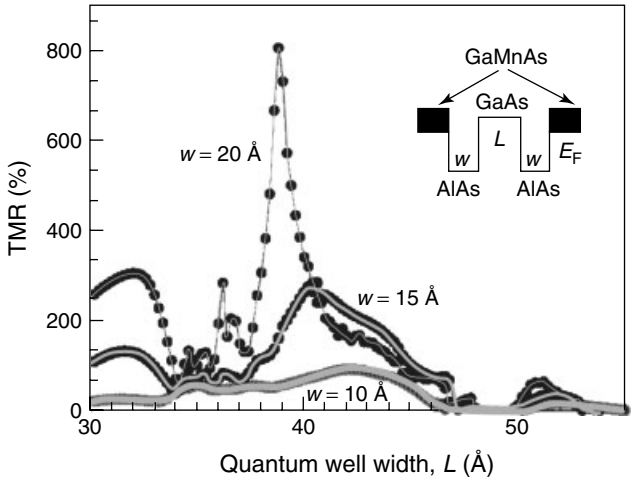

Figure 12. Calculated TMR ratios by Petukhov *et al*. as a function of the GaAs quantum well width when the AlAs thickness (w) is 1, 1.5, and 2 nm. The inset is the schematic valence band diagram of these RTD structures. (Reproduced from Petukhov *et al*., 2002, with permission from the American Physical Society. © 2002.)

investigated TMR (Hayashi, Tanaka and Asamitsu, 2000). In this RTD structure, TMR ratio of around 7% was observed at 4.2 K; when it is defined as $(R_{AP} - R_0)/R_0$, where R_{AP} and R_0 are resistances in antiparallel magnetization and in parallel magnetization at zero magnetic field, respectively. (When the TMR ratio is defined as $(R_{max} - R_{min})/R_{min}$, where R_{max} and R_{min} are the maximum and minimum resistance in the TMR loop, it is about 170% at 4.2 K). This value is higher than the TMR value observed in the GaMnAs-based single-barrier MTJ at that time (∼5%). Although the shape of the derivative $dI/dV - V$ of this RTD sample looked wavy, negative differential resistance was not clearly observed in the $I-V$ curve. It has not been clarified whether this TMR enhancement is induced by the quantum-size effect.

Mattana *et al*. fabricated a GaMnAs/AlAs (1.5 nm)/GaAs (5 nm)/AlAs (1.5 nm)/GaMnAs double-barrier MTJ structure, investigating the TMR behavior (Mattana *et al*., 2003). Figure 13(a) shows the TMR curve and (b) shows the bias dependence of TMR obtained in this double-barrier MTJ structure at 4 K. The inset of (b) shows the $I-V$ curve. Neither TMR enhancement nor negative differential resistance was observed. They explained that this is attributable to

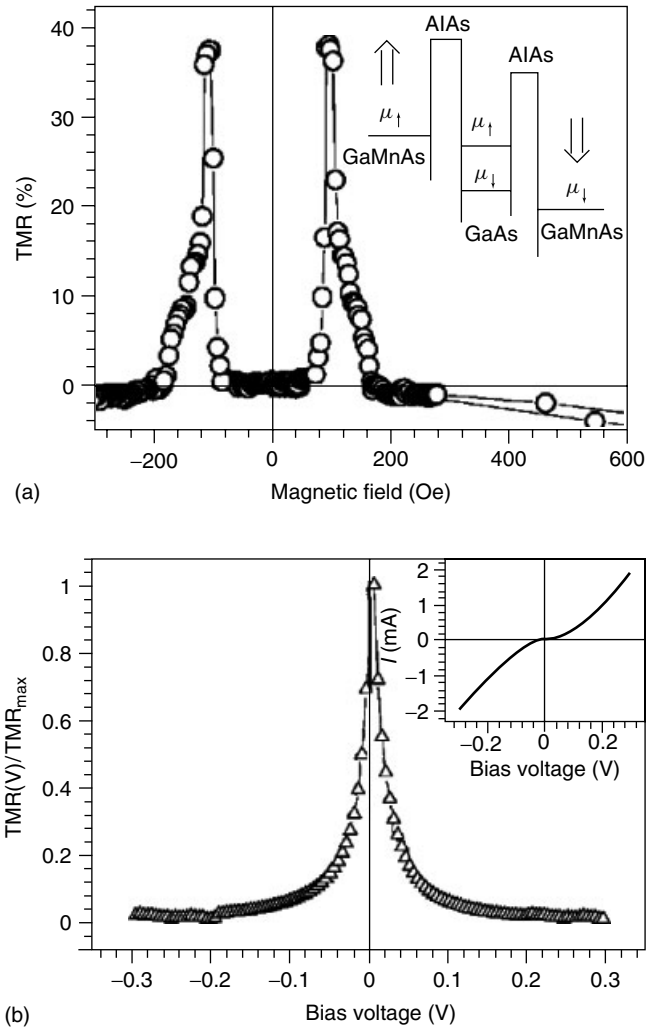

Figure 13. (a) TMR curve for a 20-μm-diameter double-barrier junction. Inset: Schematic picture of the spin splitting of the electrochemical potentials $\mu_\uparrow$, and $\mu_\downarrow$ in the nonmagnetic central layer of a GaMnAs/AlAs/GaAs/AlAs/GaMnAs structure in the antiparallel state. (b) Bias dependence of TMR obtained in the double-barrier MTJ structure at 4 K. The inset of (b) shows its I-V curve. (Reproduced from Mattana *et al*., 2003, with permission from the American Physical Society. © 2003.)

the sequential tunneling without spin relaxation in the GaAs middle layer, where the spin relaxation time is longer than the mean time τ_n spent by holes in the GaAs middle layer between tunneling in and tunneling out. Considering the tunnel resistance as a function of the barrier thickness observed by Tanaka and Higo (2001) (shown in Figure 4), τ_n is estimated to be a few 100 ps at a typical energy of some tens of millielectron volts in a few nanometer-thick quantum well. This is much longer than the time of the phase breakdown, which generally does not exceed a few picoseconds at 4 K. They concluded that this condition does not fulfill that of the coherent resonant tunneling and that sequential tunneling is dominant in their double-barrier MTJ structure.

Ohya *et al*. suggested that one of the possible reasons for the difficulty in the observation of TMR associated with the resonant tunneling effect in GaMnAs/AlAs/GaAs/AlAs/GaMnAs RTDs is its band profile. Because the valence band bottom energy of GaAs is higher than the Fermi level of GaMnAs by 87–140 meV ($\equiv v$) in terms of hole energy (Ohno, Arata, Matsukura and Ohno, 2002), the energy of the valence band bottom of the GaAs quantum well is higher than the Fermi level of GaMnAs. Therefore, a high bias voltage of at least about 200 mV ($\approx 2v/e$) has to be applied in order to observe the resonant levels formed above the valence band bottom of the GaAs quantum well. However, as shown in Figure 13(b), and reported by Mattana *et al*. (2003), when a bias voltage higher than 200 mV is applied to the GaMnAs-based double-barrier structure, the TMR ratio becomes very small or almost zero because of the strong bias dependence of TMR. Therefore, it is difficult to observe TMR and the resonant tunneling effect at the same time in this structure.

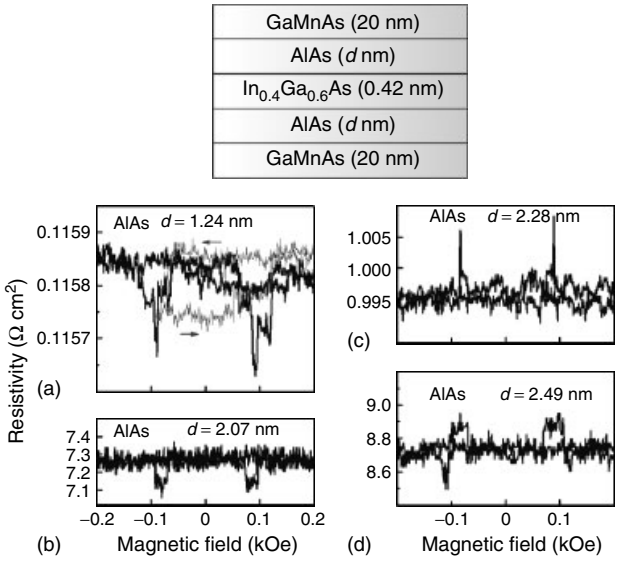

Figure 14. TMR curves of the $Ga_{0.94}Mn_{0.06}As$/AlAs (d nm)/$In_{0.4}Ga_{0.6}As$ (0.42 nm)/AlAs (d nm)/$Ga_{0.94}Mn_{0.06}As$ RTD junctions with d of (a) 1.24, (b) 2.07, (c) 2.28, and (d) 2.49 nm. The measurements were done at 7 K with a bias voltage of 10 mV and a magnetic field applied in plane along the [100] axis. In (a), bold and thin curves indicate a major loop and a minor loop, respectively (Ohya, Hai and Tanaka, 2005). (Reproduced from Ohya *et al*., 2005, with permission from the American Institute of Physics. © 2005.)

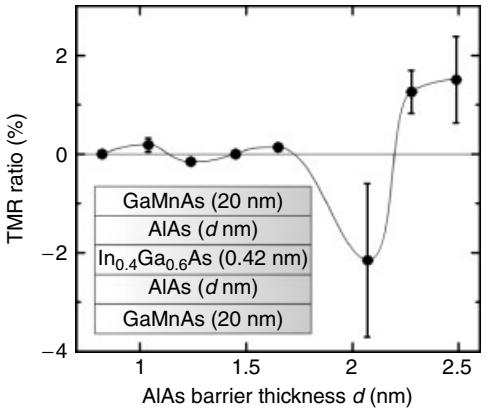

Figure 15. TMR ratio versus AlAs barrier thickness d of the $Ga_{0.94}Mn_{0.06}As$/AlAs (d nm)/$In_{0.4}Ga_{0.6}As$ (0.42 nm)/AlAs (d nm)/$Ga_{0.94}Mn_{0.06}As$ RTD. The measurements were carried out at 7 K with a bias voltage of 10 mV and a magnetic field applied in plane along the [100] axis. (Reproduced from Ohya *et al*., 2005, with permission from the American Institute of Physics. © 2005.)

For these reasons, Ohya *et al*. used an $In_{0.4}Ga_{0.6}As$ quantum well instead of GaAs. The energy of the heavy-hole band of $In_{0.4}Ga_{0.6}As$ is estimated to be about 200 meV lower than the Fermi level of GaMnAs (Van de Walle, 1989). Owing to the strong strain in the $In_{0.4}Ga_{0.6}As$ quantum well, it is difficult to grow a thick InGaAs layer, hence a very thin InGaAs quantum well of 4.2 Å was used. $Ga_{0.94}Mn_{0.06}As$/AlAs (d nm)/$In_{0.4}Ga_{0.6}As$ (0.42 nm)/AlAs (d nm)/$Ga_{0.94}Mn_{0.06}As$ RTD junctions were grown with the AlAs thickness d varied from 0.8 to 2.7 nm by controlling the in-plane position of the mobile shutter in front of the sample surface equipped with the MBE growth chamber. Figure 14(a), (b), (c), and (d) show the TMR curves of this sample with d of 1.24, 2.07, 2.28, and 2.49 nm at 7 K, respectively. In (a) and (b), usual positive TMR was obtained, while in (c) and (d) inverse TMR was observed. Figure 15 shows the TMR ratio as a function of d. With increasing d, the TMR ratio oscillated between positive and negative values with a period of around 0.8 nm.

It is difficult to explain this peculiar TMR behavior by the multiple magnetic domain formation, the impurity level in the barrier (Tsymbal, Sokolov, Sabirianov and Doudin, 2003), or the interference of two states with complex wave vectors in the barrier (Yuasa *et al*., 2004; Bultler, Zhang, Schulthess and MacLaren, 2001). The most possible mechanism for explaining this TMR behavior is the resonant

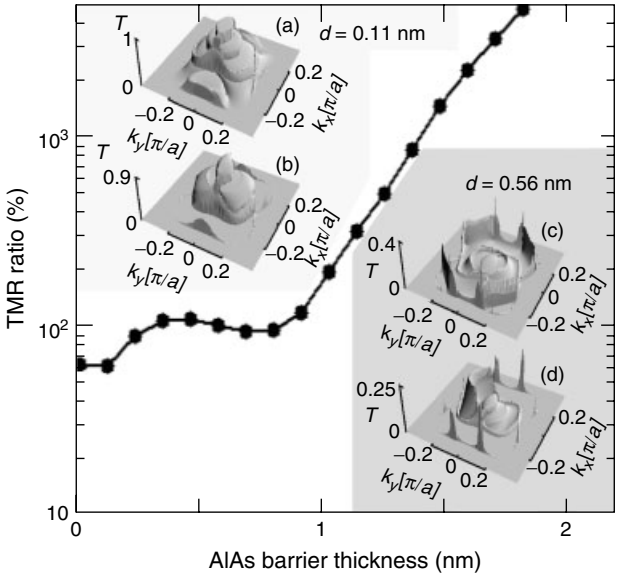

Figure 16. Calculated TMR ratio of GaMnAs/AlAs (d nm)/$In_{0.4}Ga_{0.6}As$ (0.42 nm)/AlAs (d nm)/GaMnAs RTD structures as a function of d, where exchange energy Δ and E_F are assumed to be 80 meV and 270 meV, respectively. The insets (a) and (b) show the tunneling probabilities as functions of $\mathbf{k}_\parallel$ with $d = 0.11$ nm in parallel magnetization and in antiparallel magnetization, respectively; and (c) and (d) show those with $d = 0.56$ nm in parallel magnetization and in antiparallel magnetization, respectively. (Reproduced from Ohya *et al*., 2005, with permission from the American Institute of Physics. © 2005.)

tunneling effect. To evaluate the influence of the resonant tunneling effect, the TMR ratios were calculated for the GaMnAs/AlAs/$In_{0.4}Ga_{0.6}As$/AlAs/GaMnAs RTDs using the transfer matrix method with 4×4 Luttinger–Kohn $k \cdot p$ Hamiltonian and the p–d exchange Hamiltonian (Dietl, Ohno and Matsukura, 2001). Figure 16 shows the calculated TMR ratio of GaMnAs/AlAs (d nm)/$In_{0.4}Ga_{0.6}As$ (0.42 nm)/AlAs (d nm)/GaMnAs RTD structures as a function of d when E_F is 270 meV. Inset figures are tunneling probabilities as functions of $\mathbf{k}_\parallel$ with $d = 0.11$ nm in (a) parallel and (b) antiparallel magnetization, and with $d = 0.56$ nm in (c) parallel and (d) antiparallel magnetization, respectively. The calculated TMR ratio oscillated with a period of around 0.8–1.5 nm. When d is less than 0.7 nm, the contribution of the resonant tunneling effect is small. For example, in (a) and (b), the shape of the tunneling probabilities are almost the same as those obtained in GaMnAs/AlAs/GaMnAs single-barrier heterostructures, where resonant peaks are hardly seen. Therefore, the TMR ratio decreases with increasing d like the case of GaMnAs/AlAs/GaMnAs single-barrier heterostructures, as can be seen when d is $0.4 - 0.7$ nm in Figure 16. When d becomes 0.5 nm, the resonant tunneling effect begins to occur. For example, as shown in (c) in parallel magnetization, octagon-shaped sharp resonant peaks are formed at $|\mathbf{k}_\parallel|$ around $0.2 - 0.3\pi/a$. On the other hand, as shown in (d) in antiparallel magnetization, resonant peaks are hardly formed because the $\mathbf{k}_\parallel$ region contributing to the tunneling is smaller than the octagon at which the resonant peaks are formed in parallel magnetization. As d increases above 0.7 nm, the resonant tunneling effect becomes stronger, thus the TMR ratio increases. In this way, TMR oscillation occurs. Such a TMR oscillation was obtained when E_F was higher than 210 meV, and a similar resonant tunneling effect was also obtained.

In this calculation, the oscillatory behavior was obtained, but the inverse TMR was not reproduced. This is possibly because diffusive scattering induces inverse TMR. This mechanism of inverse TMR induced by diffusive scattering was proposed by Itoh, Inoue, Umerski, and Mathon (2003), and their calculations reproduced the experimental results well in the NiFe/Al_2O_3/Cu/Co MTJ (Yuasa, Nagahama and Suzuki, 2002). In GaMnAs-based heterostructures, it is known that there are point defects, such as Mn interstitials (Yu *et al*., 2002) and As anti-site defects (Grandidier *et al*., 2000), thus this scenario may occur. However, further theoretical investigations are needed to verify it.

At present, in FMS-based quantum heterostructures, clear observation of the negative differential resistance in I–V characteristics or TMR enhancement induced by the quantum-size effect has not been accomplished. The reason has not been clarified yet. In future, more considerations on how to realize the quantum-size effect should be done, and TMR enhancement and realization of novel functions by quantum-size effect are to be expected. Very recently, TMR enhancement associated with resonant tunneling. (Ohya, Hai, Mizuno and Tanaka, 2007).

4 NOVEL PHENOMENA AND STRUCTURES RELATED TO TMR IN SEMICONDUCTORS

4.1 Tunneling anisotropic magnetoresistance (TAMR)

Recently, a novel phenomenon called TAMR was observed in GaMnAs-based heterostructures. TAMR is very similar to TMR, but the characteristics of TAMR are significantly different from those of TMR. While TMR is a phenomenon caused by the difference of the tunnel resistance between parallel and antiparallel magnetization, TAMR is a phenomenon where the tunnel resistance differs depending on the magnetization direction in GaMnAs. In contrast to TMR, which is observed in the MTJ structures composed of two FM layers, TAMR can be observed even in a 'single' FM GaMnAs layer. TAMR was observed in Au/AlO_x/GaMnAs structures

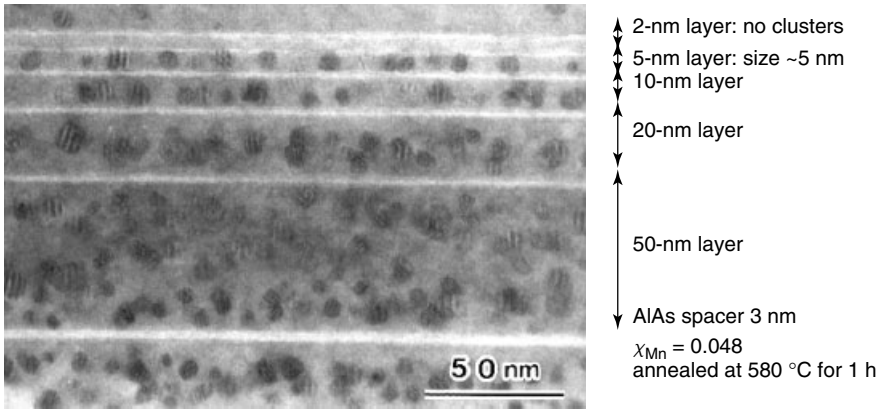

Figure 17. Cross-sectional transmission-electron microscopy (TEM) image of MnAs nanoclusters with different GaAs:MnAs thicknesses of 50, 20, 10, 5, and 2 nm. These layers are sandwiched by 3-nm-thick AlAs spacer layers. The Mn concentration is fixed at 4.8% in all the GaMnAs layers (as-grown), which turned into GaAs:MnAs layers by phase separation during annealing at 580 °C. (Reproduced from Shimizu and Tanaka, 2001, with permission from the American Institute of Physics. © 2001.)

containing only one FM GaMnAs layer (Gould *et al*., 2004). They observed spin-valve-like MR curves which are very similar to those of TMR. However, the switching field, at which the resistance state changes from low to high or high to low, and the sign of the (TA)MR ratio (∼3% at 4.2 K) change depending on the magnetic-field angle and temperature. From the measurement results of magnetic-field angle dependence of TAMR, it was clarified that the tunnel resistance becomes high when the magnetization lies along the [100] or the [$\bar{1}$00] crystallographic direction of GaMnAs, and becomes low when it is along [010] or [0$\bar{1}$0]. These results suggest that TAMR is induced by the anisotropic DOSs of GaMnAs. They calculated the anisotropic DOS of GaMnAs using the $k \cdot p$ envelope function description, and indicated that TAMR is reproduced when assuming a small in-plane uniaxial strain of around 0.1%. Because GaMnAs has a large spin-orbit interaction, such a small strain can induce the anisotropic DOS, leading to a TAMR of several percent.

Large TAMR, up to 150 000%, was observed in a GaMnAs/GaAs (2 nm)/GaMnAs MTJ structure with a bias voltage of 1 mV at 1.7 K (Rüster *et al*., 2005). As in the case of TAMR observed in the single GaMnAs layer mentioned earlier, the sign of TAMR observed in this MTJ structure also changes when the direction of the magnetic field is rotated. It was found that TAMR has a very strong bias dependence and temperature dependence. For these mechanisms, they proposed several factors, such as the zero-bias anomaly (Lee, Tejedor and Fernández-Rossier, 2004) in tunneling from a dirty metal which appears because of the opening of an Efros–Shklovskii gap (Efros and Shklovskii, 1975) at E_F when crossing the metal–insulator transition, disorder and impurity-mediated tunneling, and so on. At present, however, the mechanism of TAMR has not been completely understood yet, thus further studies are needed.

4.2 TMR in MTJ structures with MnAs nanoclusters embedded in GaAs

Recently, it was reported that FM MnAs nanoclusters embedded in GaAs, that is GaAs:MnAs, can be used as the magnetic electrode of semiconductor-based MTJs (Hai, Yokoyama, Ohya and Tanaka, 2006). GaAs:MnAs is a granular material formed by annealing GaMnAs at 500 ∼ 700 °C. It has good compatibility with III–V heterostructures (Tanaka, Shimizu and Miyamura, 2001). Also, because of the high T_C of MnAs around 313 ∼ 318 K, GaAs:MnAs-based structures are expected to be used for semiconductor-based spin-electronic devices operating at room temperature. Figure 17 shows the transmission-electron microscopy (TEM) image of the GaAs:MnAs layers sandwiched by thin AlAs layers (Shimizu and Tanaka, 2001). The black dot regions correspond to the hexagonal MnAs nanoclusters. A high-quality heterostructure without any dislocations was obtained. One important feature of the GaAs:MnAs-based heterostructures is the controllability of the size of the MnAs clusters. When the distance between the AlAs layers decreases, the size of

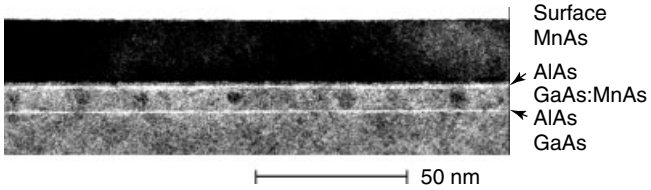

Figure 18. Cross-sectional TEM image of the MnAs (type-A, 20 nm)/GaAs (1 nm)/AlAs (2.2 nm)/GaAs:MnAs (5 nm)/AlAs (1.5 nm)/p-GaAs(001) heterostructure (from top to bottom), in which uniform (5 nm in diameter) MnAs nanoparticles are found between the two AlAs layers. (Reproduced from Hai, P. *et al*., 2006, with permission from Elsevier. © 2006.)

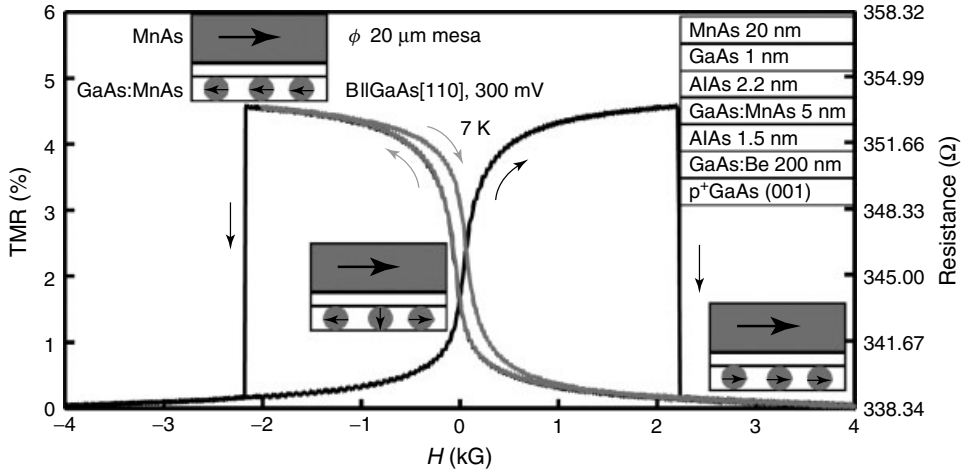

Figure 19. TMR at 7 K with a bias voltage of 300 mV of an MTJ, whose structure is MnAs (20 nm)/GaAs (1 nm)/AlAs (2.2 nm)/GaAs:MnAs (5 nm)/AlAs (1.5 nm)/p-GaAs(001). The diameter of the MTJ was 20 μm. The solid and gray curves are major and minor loops, respectively. The magnetic field was applied in the film plane and parallel to the GaAs [110] azimuth. (Reproduced from Hai, P. *et al*., 2006, with permission from Elsevier. © 2006.)

the MnAs clusters becomes uniform, because it is limited by the distance between the two AlAs layers. By using this technique, the magnetic characteristics of MnAs nanoclusters can be controlled.

Hai *et al*. fabricated MnAs (type-A, 20 nm)/GaAs(1 nm)/Al As(2.2 nm)/GaAs:MnAs(5 nm)/AlAs (1.5 nm)/p-GaAs(001) heterostructures and mesa-shaped MTJs with 20-μm diameter. Figure 18 shows cross-sectional TEM image of this MTJ structure, in which uniform (5 nm in diameter) MnAs nanoparticles are embedded between the two ultrathin AlAs layers. Figure 19 shows the TMR loops of this MTJ at 7 K with a bias voltage of 300 mV. The magnetic field was applied along the easy magnetization axis of type-A MnAs thin film, which is parallel to the in-plane GaAs [110] azimuth. Clear TMR with major and minor loops was observed. The jump of the major loop at ±2.2 kG corresponds to the abrupt magnetization reversal of the top MnAs electrode. The hysteresis of the minor loop indicates that the thermal magnetization fluctuation of the MnAs nanoclusters is quenched. The appearance of TMR shows that MnAs nanoclusters with 5-nm diameter can work as spin injectors. Figure 20 shows the bias voltage dependence of the TMR ratio. The bias polarity is defined by the voltage of the top electrode with respect to the substrate. Up to +300 mV, the TMR increases monotonously and reaches a maximum value of 4.5% at +300 mV. Over +300 mV, the TMR decreases slowly but the bias voltage V_{half} at which the TMR is reduced by half is surprisingly as high as +1200 mV. This value of V_{half} is much higher than that (∼40 mV) of FMS-based MTJs. The peak of TMR at 300 mV reflects a local maximum of spin polarization at an energy level above the Fermi level of MnAs, which is predicted by theoretical calculations (Ravindran *et al*., 1999; Pangulur *et al*., 2003). A similar picture is also observed at the negative biases. The appearance of

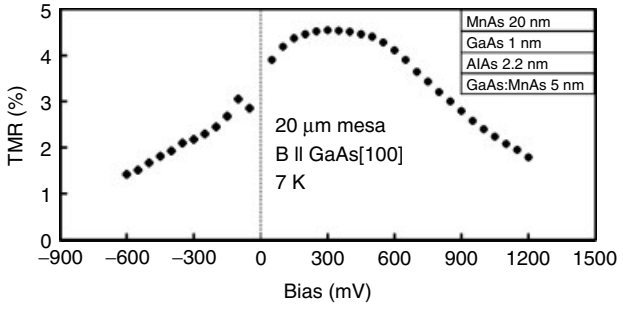

Figure 20. Bias voltage dependence of TMR of the same MTJ of Figure 19 at 7 K. The magnetic field is applied in the film plane and parallel to the GaAs [110] azimuth. The V_{half} is as high as 1200 mV. (Reproduced from Hai, P. *et al*., 2006, with permission from Elsevier. © 2006.)

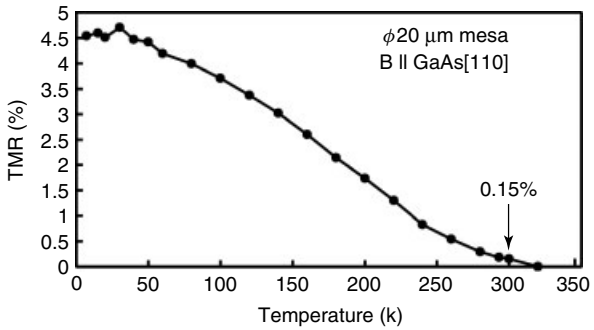

Figure 21. Temperature dependence of TMR of the same MTJ of Figure 19. TMR was observed up to room temperature. (Reproduced from Hai, P. *et al*., 2006, with permission from Elsevier. © 2006.)

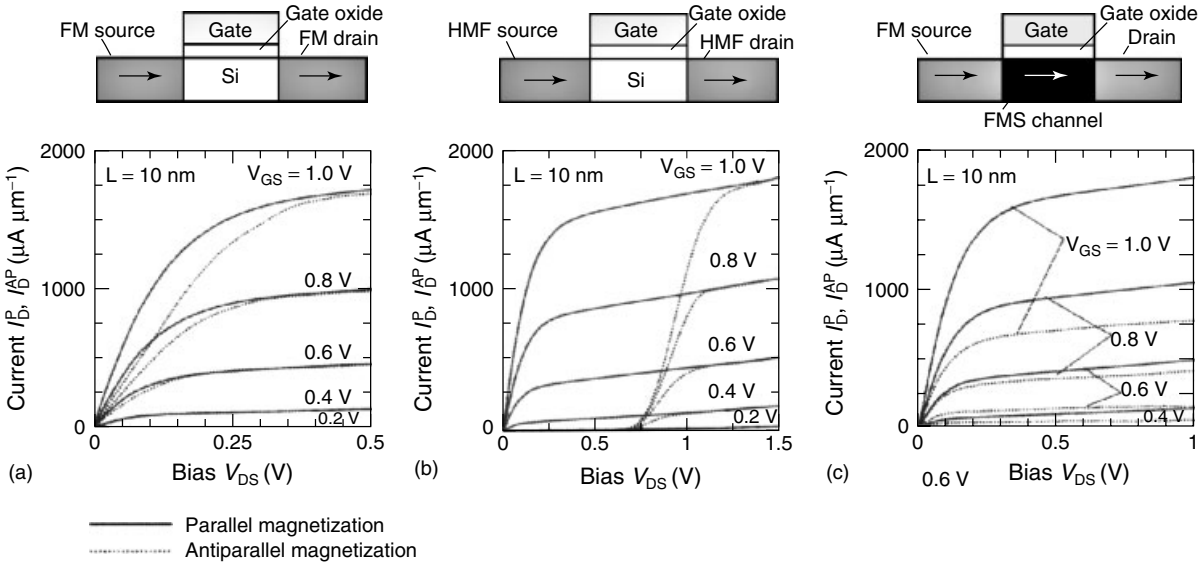

Figure 22. Schematic device structures and output characteristics of the spin MOSFETs. The devices have (a) ferromagnetic-metal (FM) source and drain and Si channel; (b) half-metallic ferromagnet (HMF) source and drain, and Si channel; (c) FM source and drain, and ferromagnetic semiconductor (FMS) channel. Each device has a MOS gate. The drain current I_{D^-} drain-source voltage V_{DS} characteristics in parallel and antiparallel magnetization are plotted by solid and broken curves, respectively, with various gate-source biases V_{GS}. (Reproduced from Sugahara and Tanaka, 2004; Matsuno *et al*., 2004, with permission from the American Institute of Physics. © 2004.)

TMR at negative biases shows that MnAs nanoclusters can also work as spin detectors. Figure 21 shows the temperature dependence of TMR. TMR was observed up to room temperature and remains at 300 K. Theoretically, the TMR value increases by increasing the size of the MnAs clusters. Higher TMR ratio is expected to be obtained in the future.

4.3 TMR in spin transistor structures

A recently proposed metal-oxide-semiconductor field-effect-transistor (MOSFET) type of spin transistor, referred to as spin MOSFET, is expected to give new functionalities in semiconductor integrated electronics (Sugahara and Tanaka, 2004; Matsuno, Sugahara and Tanaka, 2004). The spin MOSFET has a simple device structure consisting of an ordinary MOS structure and FM (or half-metallic) contacts for the source/drain, resulting in good compatibility with well-established Si technology. Figure 22 shows the structures of the spin MOSFET. In this device, spin-polarized carriers are injected from the source through the Schottky tunnel barrier at the FM source/channel contact into the semiconductor channel, are transported in the channel keeping the spin polarization, and reach the drain. It can be regarded as a three terminal device with magnetoresistance (or TMR) and transistor functions (Sugahara, 2005; Sugahara and Tanaka, 2006).

The most important feature of the spin MOSFET is magnetization-dependent output characteristics: The current-drive capability of the spin MOSFET can be controlled by the relative magnetization configuration of the two FM components in the device (for example the source and the drain in Figure 22a and b), that is, the output current (or current-drive capability) is large (small) in parallel (antiparallel) magnetization, as shown in the lower panel of Figure 22. Furthermore, it is predicted from theoretical calculations that the spin MOSFET exhibits excellent transistor performance, such as high transconductance and low power-delay product that are important requirements for integrated circuit applications. These features make the spin MOSFET a functional building-block device for nonvolatile memory and reconfigurable logic (Sugahara, 2005; Tanaka, 2005; Sugahara and Tanaka, 2006).

Here we show how the TMR effect is used in the spin transistors, taking the structure of Figure 22(c) as an example, where the device has a MOS structure with an FMS channel, and a FM source and drain, as shown in Figure 23 (Sugahara and Tanaka, 2005). The interfaces between the FM source/drain and the FMS channel are Schottky junctions. (It is not necessary that both the source and the drain are FM/FMS Schottky junctions.) A nonmagnetic metal/FMS Schottky junction can be used for one of the source and drain contacts. Possible candidates for the channel materials are FMSs using Si, Ge, and SiGe as host material. Recently, it has been well recognized that SiGe and Ge, as well as Si and strained Si, are important as channel materials for advanced MOSFETs with high performance. $Si_{1-x}Mn_x$ and $Ge_{1-x}Mn_x$ are theoretically predicted to be FMSs (Araki, Sato and Katayama-Yoshida, 2002; Araki, Shirai, Sato and

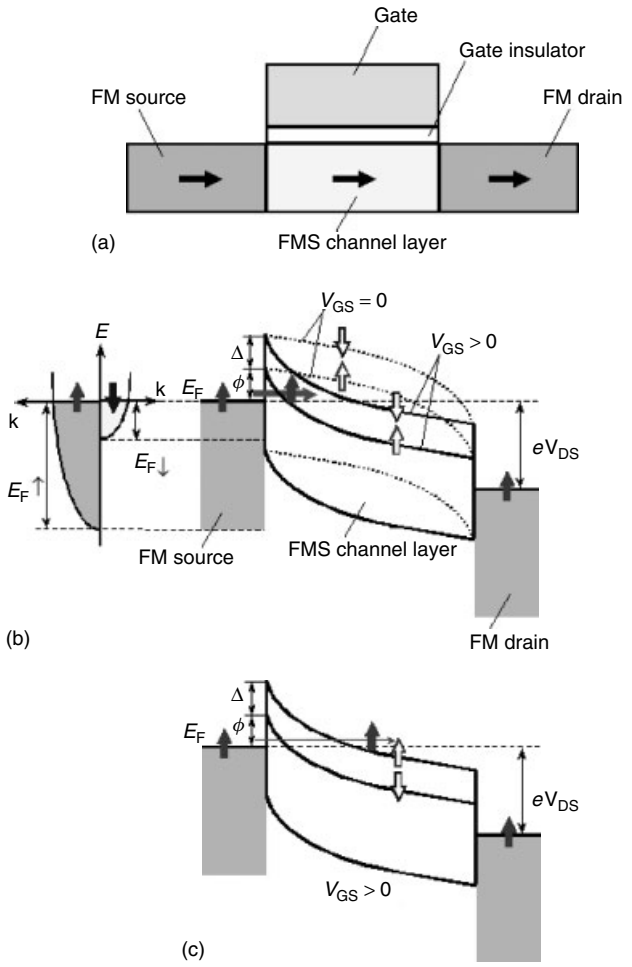

Figure 23. Schematic (a) device structure and (b), (c) band diagrams of an *n*-channel accumulation-type spin MOSFET with the channel of a nondegenerate ferromagnetic semiconductor (FMS); (b) and (c) show parallel and antiparallel magnetization configurations, respectively. (Reproduced from Sugahara *et al*., 2005, with permission from IEEE. © 2005.)

Katayama-Yoshida, 2003; Stroppa, Picozzi, Continenza and Freeman, 2003), and experimental investigations have been performed by several groups. The successful epitaxial growth of FM $Ge_{1-x}Mn_x$ films and their field-effect control of ferromagnetism were demonstrated (Park *et al*., 2002; D'Orazio *et al*., 2003). High Curie temperatures close to room temperature were also reported for $Ge_{1-x}Mn_x$ and $Ge_{1-x-y}Mn_xCo_y$ (Cho *et al*., 2002; Tsui *et al*., 2003). Recently reported n-type iron silicide–based FMSs, $Fe_xCo_{1-x}Si$ and $Fe_xMn_{1-x}Si$ (Manyala *et al*., 2004), may also be candidates for the channel material. Possible materials for the source/drain are FMs with a large spin polarization, such as iron-based alloys and half-metallic ferromagnets (HMFs). CoFe and CoFeB are commonly used in MTJs as the FM electrodes, which exhibit a large TMR, indicating a large spin polarization (Han *et al*., 2000; Wang *et al*., 2004; Maehara, Djayaprawira, Nagai and Watanabe, 2006). Fe_3Si is also an attractive candidate (Nakane, Tanaka and Sagahara, 2006), since Fe_3Si is a Heusler alloy and thus half-metallicity or an extremely large spin polarization is expected. Recently, a high-spin injection efficiency from Fe_3Si into a semiconductor was reported using an Fe_3Si/GaAs Schottky junction (Ramsteiner *et al*., 2004).

In the following, an *n*-channel accumulation-type spin MOSFET with the channel of a nondegenerate FMS is presented to explain its operating principle. Hereafter, it is assumed that the FMS channel is a free layer and the FM source/drain is a pinned layer, and that the magnetization direction of the FM drain is always the same as that of the FM source. Figure 23(b) schematically shows the band diagram of the spin MOSFET under a common source bias condition with and without a gate–source bias V_{GS}, where the relative magnetization configuration of the FMS channel and FM source/drain is parallel. Assuming that the nonmagnetic metal/FMS Schottky junction model given by Lebedeva and Kuivalainen (Lebedeva and Kuivalainen, 2003) can be extended to the FM/FMS Schottky junction, a spin-dependent Schottky barrier (SB) appears due to the energy splitting Δ of the up- and down-spin bands at the conduction band edge of the FMS channel, that is, a lower SB height ϕ for up-spin electrons and a higher SB height $\phi + \Delta$ for down-spin electrons, as shown in Figure 23(b). When a drain–source bias $V_{DS}(>0)$ is applied with $V_{GS} = 0$, neither up-spin nor down-spin electrons are injected from the source to the channel because of the reverse-biased SB of the source (as shown by the upper two dotted curves in Figure 23b). By applying $V_{GS}(>0)$, the SB width is reduced (as shown by the upper two solid curves in Figure 23b), and thus up- and down-spin electrons in the FM source can tunnel through the thinned SB into the channel. When the magnetization configuration of the FMS channel and FM source is parallel, the SB height is low for the majority spin (up spin) electrons in the FM source. Thus, a large output (drain) current can flow. When the magnetization configuration becomes antiparallel because of flipping the magnetization of the FMS channel, the SB height for the majority spin electrons in the FM source is higher, as shown in Figure 23(c). Thus, current by majority spin electrons is drastically reduced, since the tunnel current decreases exponentially as the barrier height increases. Although the SB height is lower for the minority spin (down spin) electrons in the FM source, tunneling current through the SB is small due to the small carrier density of the minority spin electrons. Therefore, the output current depends on the relative magnetization of the FMS channel and FM source/drain, as shown in Figure 22(c). A large magnetocurrent ratio can be obtained and it is insensitive to the drain–source bias conditions, owing to the spin filter effect of the FMS/FM Schottky junction.

Furthermore, excellent transistor performance such as high transconductance and small subthreshold swing is predicted. This device can be applied to a new nonvolatile memory architecture using a single spin MOSFET cell, in which the programming current can be drastically reduced using the electrical manipulation of magnetization reversal of the FMS channel (Sugahara and Tanaka, 2005).

Spin-dependent Tunneling: Role of Evanescent and Resonant States

Evgeny Y. Tsymbal
University of Nebraska, Lincoln, NE, USA

1 INTRODUCTION

The phenomenon of spin-dependent tunneling (SDT) is an imbalance in the electric current carried by up- and down-spin electrons tunneling from a ferromagnetic metal through an insulating barrier. The field of SDT was founded by the pioneering experiments of Tedrow and Meservey (1971, 1973). They used ferromagnet/insulator/superconductor (FM/I/S) tunnel junctions and measured the spin polarization (SP) of the tunneling current originating from various ferromagnetic metals across an amorphous alumina barrier (Meservey and Tedrow, 1994).

The phenomenon of tunneling magnetoresistance (TMR), first observed in experiments by Jullière (1975), is the manifestation of SDT in magnetic tunnel junctions (MTJs). An MTJ consists of two ferromagnetic metal electrodes separated by a thin insulating barrier layer. The most important property of an MTJ is that the tunneling current across the barrier depends on the relative orientation of the magnetizations of the two ferromagnetic electrodes, which can be changed by an applied magnetic field. This phenomenon is called *tunneling magnetoresistance* (*TMR*). The discovery of a large reproducible TMR at room temperature in MTJs based on amorphous Al_2O_3 by Moodera, Kinder, Wong, and Meservey (1995) has attracted considerable interest due to the potential application of MTJs in spin-electronic devices such as magnetic sensors and magnetic random access memories (MRAMs). This interest was further boosted by a recent discovery of large TMR values in crystalline Fe/MgO/Fe and similar MTJs by Parkin *et al.* (2004) and Yuasa *et al.* (2004), and triggered tremendous activity in the experimental and theoretical investigations of the electronic, magnetic, and transport properties of MTJs (for reviews on MTJs see Levy and Zhang (1999), Moodera and Mathon (1999), Tsymbal, Mryasov and LeClair (2003), Zhang and Butler (2003), Heiliger, Zahn and Mertig (2006) and Parkin (2006)).

Theoretical understanding of SDT has an interesting history. Tedrow and Meservey analyzed their experiments in terms of SDT currents carried from a ferromagnet through an amorphous alumina barrier into the up- and down-spin states of a superconductor (Tedrow and Meservey, 1971, 1973). They measured a SP of the tunneling conductance which is defined by

$$P = \frac{G^{\uparrow} - G^{\downarrow}}{G^{\uparrow} + G^{\downarrow}} \tag{1}$$

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

where $G^{\uparrow}$ and $G^{\downarrow}$ are the up- and down-spin conductance of the tunnel junction. The results of these early experiments on SDT were interpreted in terms of spin-dependent density of states (DOS) of the ferromagnetic electrodes at the Fermi energy, $\rho_{\mathrm{F}}^{\uparrow}$ and $\rho_{\mathrm{F}}^{\downarrow}$. Assuming that the spin-dependent conductance is proportional to $\rho_{\mathrm{F}}^{\uparrow}$ for majority-spin electrons and is proportional to $\rho_{\mathrm{F}}^{\downarrow}$ for minority-spin electrons, the measured values of the SP of the tunneling conductance, P, should be equal to the SP of the DOS at the Fermi energy of the ferromagnet,

$$P_{\mathrm{FM}} = \frac{\rho_{\mathrm{F}}^{\uparrow} - \rho_{\mathrm{F}}^{\downarrow}}{\rho_{\mathrm{F}}^{\uparrow} + \rho_{\mathrm{F}}^{\downarrow}} \tag{2}$$

This result demonstrates, however, inconsistency between the measured and predicted values of the SP. Experimentally it was found that the SP of the tunneling conductance from all the 3d ferromagnetic metals and their alloys is positive, which implies that the majority-spin electrons tunnel more efficiently than the minority-spin electrons (Meservey and Tedrow, 1994). This is in the contradiction with the bulk band structure, at least, for the two ferromagnetic metals, Co and Ni, which have the dominant contribution of the minority spins at the Fermi energy causing the respective SP of the DOS to be negative. This fact was later explained by Stearns (1977), who assumed that the most dispersive bands provide essentially all the tunneling current. On the basis of this argument and using a realistic band structure of Fe and Ni, Stearns was able to explain experimental values (measured at that time) of the SP for these ferromagnets. Despite the success of Stearns' idea, this model did not provide a clear understanding of the origin of the dominance of the 'itinerant' electrons in transport properties.

The relationship between SDT and TMR was explained by Jullière within a simple model assuming that the SP of the tunneling current is determined solely by the SP of the electronic DOS of the ferromagnetic electrodes at the Fermi energy (Jullière, 1975). Although Jullière's model served as a useful basis for interpreting a number of experiments on TMR, this model is too simple to describe all the available experimental data. In particular, experimental results show that the tunneling SP strongly depends on the structural quality of MTJs. Improvements in the quality of the alumina barrier and the metal/alumina interfaces resulted in the enhancement of the measured values of the SP (Monsma and Parkin, 2000). Experiments also show that the SP depends on the choice of the tunneling barrier. De Teresa *et al*. (1999a,b) found that Co exhibits a negative value of the SP when tunneling occurs through a $SrTiO_3$ barrier. This is opposite to the tunneling SP across an Al_2O_3 barrier, for which all 3d ferromagnets show positive SPs. Also, experiments by LeClair *et al*. demonstrated the decisive role of the electronic structure of the interfaces in SDT (LeClair *et al*., 2000, 2001a,b). It is evident, therefore, that the tunneling SP is *not* an intrinsic property of the ferromagnet alone but depends on the structural and electronic properties of the entire junction including the insulator and the ferromagnet/insulator interfaces.

More recent theoretical studies provided a new insight into the phenomenon of SDT. It was stated that the expected spin dependence of the tunneling current can be deduced from the symmetry of the Bloch states in the bulk ferromagnetic electrodes and the complex band structure of the insulator (MacLaren, Zhang, Butler and Wang, 1999; Mavropoulos, Papanikolaou and Dederichs, 2000). By identifying those bands in the electrodes that are coupled efficiently to the evanescent states decaying most slowly in the barrier, one can make conclusions about the SP of the conductance. It was emphasized that for a broad class of insulating materials the states that belong to the identity representation should have minimum decay rates. This representation is comparable to the s character suggesting that s bands should be able to couple most efficiently across the interface and decay most slowly in the barrier. For Fe, Co, and Ni ferromagnets the majority-spin states at the Fermi energy have more s character than the minority-spin states, which tend to have mainly d character. Thus, the majority conductance is expected to be greater than the minority conductance resulting in a slower decay with barrier thickness for the former. These symmetry arguments satisfactorily explain large values of TMR predicted for epitaxial Fe/MgO/Fe junctions (Butler, Zhang, Schulthess and MacLaren, 2001; Mathon and Umerski, 2001). These conclusions are also expected to be valid for MTJs with an Al_2O_3 barrier which is consistent with the experimental observations (Meservey and Tedrow, 1994). They are also in agreement with the earlier hypothesis by Stearns (1977).

Despite the undoubted importance, the symmetry arguments have their limitations. First, they assume that the barrier is sufficiently thick so that only a small focused region of the surface Brillouin zone contributes to the tunneling current. For realistic MTJs with barrier thickness of about 1 nm this assumption is usually unjustified. Moreover, for amorphous barriers like alumina where the transverse wave vector is not conserved in the process of tunneling, the entire surface Brillouin zone might contribute almost equally to the conductance. Second, despite the presence of certain selection rules for tunneling, there is no general rule preventing the Bloch states composed mostly of the d orbitals from tunneling through the barrier states that have no d character. For example, it was demonstrated experimentally that the tunneling current from a ferromagnetic Ni tip (Alvarado and Renaud, 1992) and from a hcp Co(0001) surface (Okuno, Kishi and Tanaka, 2002) through vacuum is negatively spin

polarized. The negative SP is due to the dominant contribution of the d electrons in tunneling, despite the fact that there are no d states in vacuum. Therefore, symmetry considerations alone applied to bulk materials are not always sufficient to predict the SP. It is critical to take into account the electronic structure of the ferromagnet/barrier interfaces which, as was shown experimentally, control the SP (LeClair *et al*., 2000, 2001a,b).

An important mechanism by which the interfaces affect the SP of the conductance is the bonding between the ferromagnetic electrodes and the insulator (Tsymbal and Pettifor, 1997). The interface bonding determines the effectiveness of transmission across the interface, which can be different for electrons of different orbital character (and/or symmetry) carrying an unequal SP. Also the interface bonding is responsible for the appearance of interface states which, as was predicted theoretically (Wunnicke *et al*., 2002), affect the conductance dramatically. Experimentally, the effect of bonding at the ferromagnet/insulator interface was proposed to explain the inversion of the SP of electrons tunneling from Co across a $SrTiO_3$ barrier (De Teresa *et al*., 1999a,b). The bonding mechanism was also put forward to elucidate positive and negative values of TMR depending on the applied voltage in MTJs with Ta_2O_5 and Ta_2O_5/Al_2O_3 barriers (Sharma, Wang and Nickel, 1999). Interface states in MgO-based tunnel junctions were indirectly observed in transport measurements (Tiusan *et al*., 2004, 2006). Theoretically, strong sensitivity of the magnitude of TMR to the sp–d mixing at the ferromagnet/alumina interface was predicted in the presence of imperfectly oxidized Al or O ions (Itoh and Inoue, 2001). It was found that oxygen deposited on the Fe(001) surface reverses the SP of the DOS in vacuum due to the strong exchange splitting of the antibonding oxygen states (Tsymbal, Oleinik and Pettifor, 2000). It was predicted that an atomic layer of iron oxide at the interface between Fe and MgO layers greatly reduces TMR in Fe/MgO/Fe junctions because of the bonding between Fe and O atoms (Zhang, Butler and Bandyopadhyay, 2003). The significant effect of the interface atomic structure on current–voltage characteristics was predicted for Fe/MgO/Fe junctions (Heiliger, Zahn, Yavorsky and Mertig, 2006).

The main objective of this article is to discuss two important factors that control the SP in MTJs: the complex band structure of the insulating barrier which determines selection rules for tunneling of spin-polarized bands from ferromagnets and the bonding at the ferromagnet/barrier interface resulting in the appearance of resonant interface states that significantly affect the SP of the conductance. We consider several theoretical models illustrating the significance of these two mechanisms in different kinds of MTJs. We start our discussion from Jullière's model and a simple description of SDT within a free-electron model.

2 JULLIÈRE'S MODEL

Jullière's model for TMR is based on two assumptions. First, it assumes that spin of electrons is conserved in the tunneling process. It follows, then, that tunneling of up- and down-spin electrons are two independent processes, so that the conductance occurs in the two independent spin channels. Such a two-current model has also been used to interpret the closely related phenomenon of giant magnetoresistance (see, Tsymbal and Pettifor, 2001 for a review). According to this assumption, electrons originating from one spin state of the 'left' ferromagnetic electrode are accepted by unfilled states of the same spin of the 'right' electrode. If the two ferromagnetic films are magnetized parallel, the minority spins tunnel to the minority states and the majority spins tunnel to the majority states. If, however, the two films are magnetized antiparallel, the identity of the majority- and minority-spin electrons is reversed so that the majority spins of the left electrode tunnel to the minority states in the right electrode and vice versa. Second, Jullière's model assumes that the conductance for a particular spin orientation is proportional to the product of the DOS of the two ferromagnetic electrodes. According to these assumptions, the conductance for the parallel and antiparallel alignment, G_P and G_{AP} respectively, can be written as follows:

$$\begin{aligned} G_P &\propto \rho_L^{\uparrow}\rho_R^{\uparrow} + \rho_L^{\downarrow}\rho_R^{\downarrow} \\ G_{AP} &\propto \rho_L^{\uparrow}\rho_R^{\downarrow} + \rho_L^{\downarrow}\rho_R^{\downarrow} \end{aligned} \tag{3}$$

where $\rho_n^{\uparrow}$ and $\rho_n^{\downarrow}$ are the DOS of the left and right ferromagnetic electrodes (designated by index n = L, R) for the majority- and minority-spin electrons. It follows from equation (3) that the parallel- and antiparallel-magnetized MTJs have different conductances, which implies a nonzero TMR. If we define a TMR ratio as the conductance difference between parallel and antiparallel magnetizations, normalized by the antiparallel conductance, we arrive then at Jullière's formula

$$TMR \equiv \frac{G_P - G_{AP}}{G_{AP}} = \frac{2P_L P_R}{1 - P_L P_R} \tag{4}$$

which expresses the TMR in terms of the SPs of the two ferromagnetic electrodes

$$P_n = \frac{\rho_n^{\uparrow} - \rho_n^{\downarrow}}{\rho_n^{\uparrow} + \rho_n^{\downarrow}} \tag{5}$$

where n = L, R.

This approach allows linking the known values of the SP obtained from the Tedrow–Meservey experiments to the values of TMR. It is important to note, however, that the

correlation between the SP and TMR using equation (4) disregards the nature of the DOS entering equation (3). As long as the conductance per spin can be represented as a product of two quantities characterizing the left and right electrodes (and may be left and right interfaces), we arrive at equation (4) for TMR and equation (5) for the SP. Therefore, $\rho_{\rm n}^{\uparrow}$ and $\rho_{\rm n}^{\downarrow}$ can be interpreted as an *effective* tunneling DOS of the ferromagnetic electrodes which make the applicability of Jullière's formula more general.

It appears that the most recent SP values with Al_2O_3 barriers obtained via the SDT technique agree well with the maximum TMR values reported with Al_2O_3 barriers within Jullière's model (see Tsymbal, Mryasov and LeClair, 2003 for details). The possible reason for this agreement is discussed in the next section. However, we caution that Jullière's model is only a phenomenological guide to estimate the magnitude of the TMR effect when SPs of the tunneling current across the *same* barriers are known.

3 A FREE-ELECTRON MODEL

A little more insight into TMR can be obtained using a simple free-electron model for tunneling through a rectangular potential barrier. Within this model the exchange splitting of the free-electron bands is included by using different potentials for the up- and down-spin electrons, $V_{\rm n}^{\sigma}$, where index ${\rm n}={\rm L}$, R denotes the left or right ferromagnetic electrode and σ is the spin index, $\sigma=\uparrow,\downarrow$. A solution for the free-electron model can be obtained taking into account the fact that the transverse wave vector $\mathbf{k}_{\parallel}$ is conserved in the tunneling process. Assuming that the barrier thickness d is not too small, the transmission coefficient per spin is given by

$$T^{\sigma}(\mathbf{k}_{\parallel}) = 16\kappa^2 \frac{k_{\rm L}^{\sigma}}{\kappa^2 + k_{\rm L}^{\sigma 2}} \frac{k_{\rm R}^{\sigma}}{\kappa^2 + k_{\rm R}^{\sigma 2}} e^{-2\kappa d} \tag{6}$$

Equation (6) assumes that transmission occurs between two bulk states in the ferromagnetic electrodes that are characterized by the wave vector normal to the interfaces $k_{\rm n}^{\sigma} = \sqrt{(2m/\hbar^2)(E_{\rm F} - V_{\rm n}^{\sigma}) - k_{\parallel}^2}$. $\kappa = \sqrt{(2m/\hbar^2)(U - E_{\rm F}) + k_{\parallel}^2}$ is the decay constant in the barrier, and U is the potential barrier height. As follows from equation (6), for a given value of $\mathbf{k}_{\parallel}$ the transmission coefficient can be decoupled into the product of two interface transmission functions $T_{\rm L}^{\sigma}(\mathbf{k}_{\parallel})$ and $T_{\rm R}^{\sigma}(\mathbf{k}_{\parallel})$ characterizing the left and right electrodes interfaces respectively and the exponential decay factor (see Zhang and Butler, 2003 and Belashchenko *et al.*, 2004 for discussion of the validity of this approximation in a more general case)

$$T^{\sigma}(\mathbf{k}_{\parallel}) = T_{\rm L}^{\sigma}(\mathbf{k}_{\parallel}) e^{-2\kappa d} T_{\rm R}^{\sigma}(\mathbf{k}_{\parallel}) \tag{7}$$

where

$$T_{\rm n}^{\sigma}(\mathbf{k}_{\parallel}) = \frac{4\kappa k_{\rm n}^{\sigma}}{\kappa^2 + k_{\rm n}^{\sigma 2}} \tag{8}$$

The physical meaning of $T_{\rm n}^{\sigma}(\mathbf{k}_{\parallel})$ is the transmission probability from the left (right) electrode to the barrier across the interface. For a given value of $\mathbf{k}_{\parallel}$ the interface transmission function determines the transport SP of the ferromagnet/interface.

The total spin-resolved conductance G^{σ} is determined by the sum of equation (6) over transverse wave vectors $\mathbf{k}_{\parallel}$

$$G^{\sigma} = \frac{e^2}{h} \sum_{\mathbf{k}_{\parallel}} T^{\sigma}(\mathbf{k}_{\parallel}) \tag{9}$$

This implies that, in general, the total conductance is not factorized, which makes Jullière's formula (4) inapplicable. However, for a sufficiently thick barrier only electronic states that lie in the vicinity $\mathbf{k}_{\parallel}=0$ primarily contribute the conductance because of the dependence of the decay constant κ on $k_{\parallel}$. In this case the total conductance is proportional to the product of $T_{\rm L}^{\sigma}(\mathbf{k}_{\parallel}=0)$ and $T_{\rm R}^{\sigma}(\mathbf{k}_{\parallel}=0)$, and Jullière's formula becomes valid if the effective SP of the two ferromagnetic electrodes are defined by

$$P_{\rm n} = \frac{T_{\rm n}^{\uparrow}(\mathbf{k}_{\parallel}=0) - T_{\rm n}^{\downarrow}(\mathbf{k}_{\parallel}=0)}{T_{\rm n}^{\uparrow}(\mathbf{k}_{\parallel}=0) + T_{\rm n}^{\downarrow}(\mathbf{k}_{\parallel}=0)} \tag{10}$$

where ${\rm n}={\rm L}$, R. Equation (10) is identical to Slonczewski's result (Slonczewski, 1989):

$$P_{\rm n} = \frac{k_{\rm n}^{\uparrow} - k_{\rm n}^{\downarrow}}{k_{\rm n}^{\uparrow} + k_{\rm n}^{\downarrow}} \frac{\kappa^2 - k_{\rm n}^{\uparrow} k_{\rm n}^{\downarrow}}{\kappa^2 + k_{\rm n}^{\uparrow} k_{\rm n}^{\downarrow}} \tag{11}$$

Note that here $k_{\rm n}^{\uparrow,\downarrow} = \sqrt{(2m/\hbar^2)(E_{\rm F} - V_{\rm n}^{\uparrow,\downarrow})}$ are the spin-dependent Fermi wave vectors, and $E_{\rm F}$ is the Fermi energy. As follows from equation (11), the SP of the tunneling current is not uniquely defined by the wave vector of the ferromagnet and contains a factor that depends on the barrier height. For a high potential barrier ($\kappa \gg k_{\rm n}^{\uparrow}, k_{\rm n}^{\downarrow}$) this expression reduces to

$$P_{\rm n} = \frac{k_{\rm n}^{\uparrow} - k_{\rm n}^{\downarrow}}{k_{\rm n}^{\uparrow} + k_{\rm n}^{\downarrow}} \tag{12}$$

which might be considered as the original definition of the SP within Jullière's formula in terms of bulk DOS of the ferromagnet at the Fermi energy. Indeed, within a free-electron model the bulk DOS is proportional to the Fermi wave vector which makes equations (12) and (5) identical.

In real experiments, however, the barriers may not be sufficiently thick to provide the only contribution to the conductance from electrons tunneling normal to the interfaces. In this case the SP depends on the barrier thickness and height due to the redistribution of tunneling electrons in the $\mathbf{k}_{||}$ space which makes Jullière's formula inapplicable (MacLaren, Zhang and Butler, 1997). This fact makes it surprising that Jullière's formula provides a reasonable agreement between measured values of the tunneling SP and the TMR values measured for alumina barriers.

The likely reason for this consistently is the fact that alumina barrier is amorphous. In this case, it is natural to expect that the transmission through the insulator is nonzero between states in the electrodes characterized by different values of $\mathbf{k}_{||}$. In the limit of strong disorder, scattering in the insulator becomes random and hence the transmission between $\mathbf{k}_{||}$ states occurs with equal probability. In this case the total conductance is proportional to a product of the average transmission functions characterizing the left and right interfaces

$$G^{\sigma} \propto \left\langle T_{\mathrm{L}}^{\sigma} \right\rangle \left\langle T_{\mathrm{R}}^{\sigma} \right\rangle \tag{13}$$

where $\left\langle T_{\mathrm{n}}^{\sigma} \right\rangle = \sum_{\mathbf{k}_{\|}} T_{\mathrm{n}}^{\sigma}(\mathbf{k}_{\|})$ and n = L, R. Thus the effective tunneling DOS entering the expression for polarization (5) in Jullière's formula is determined by the average interface transmission functions so that

$$P_{\mathrm{n}} = \frac{\left\langle T_{\mathrm{n}}^{\uparrow} \right\rangle - \left\langle T_{\mathrm{n}}^{\downarrow} \right\rangle}{\left\langle T_{\mathrm{n}}^{\uparrow} \right\rangle + \left\langle T_{\mathrm{n}}^{\downarrow} \right\rangle} \tag{14}$$

This explains the agreement between the SPs measured in Tedrow–Meservey experiments with values of TMR obtained using Jullière's formula (see Belashchenko *et al.*, 2004 for further discussion).

Although free-electron models capture some important features of SDT, they cannot be used for the quantitative description of TMR. In particular, free-electron models ignore the multiband electronic structure of the ferromagnetic electrodes and the ferromagnet/insulator interfaces. Also the free-electron models do not take into account the complex band structure of the insulator that, as we will see in the next section is decisive for selecting bands which tunnel most efficiently across the barrier.

4 COMPLEX BAND STRUCTURE AND SYMMETRY

A powerful method to make qualitative predictions about SDT in epitaxial tunnel junction taking into account a multiband electronic structure was proposed by Mavropoulos, Papanikolaou, and Dederichs (2000). Using a notion of the complex band structure they emphasized the importance of symmetry of the evanescent gap states in the tunneling barrier for SDT. Below we describe the basic idea of this method.

Electronic transport in tunnel junctions is largely determined by the electronic properties of the insulator within the band gap. These properties are described by a complex band structure and evanescent electronic states. Although such states can exist only at a surface or interface, their general properties can be derived from the bulk band structure of the material by letting the wave vector to be complex. Perfect epitaxial tunnel junctions have two-dimensional periodicity and therefore the wave vector, $\mathbf{k}_{||}$, parallel to the interface is conserved. For each (real) value of $\mathbf{k}_{||}$ one can then describe the evanescent states in terms of dispersion relations $E(k_{\mathrm{z}})$, where $k_{\mathrm{z}} = q + i\kappa$ is the complex wave vector perpendicular to the interface. The imaginary part κ is the decay rate, so that the corresponding wave functions fall off exponentially as $e^{-\kappa z}$. Obviously, those evanescent states that have reasonably small decay rate play the decisive role in electron tunneling. In fact, in the limit of large barrier thickness the state with the smallest decay rate, $\kappa_{\min}$, controls the tunneling current.

Similar to real bands, complex bands can be described in terms of irreducible representations of the symmetry group. Symmetry of the evanescent states determines which Bloch states of the metal electrodes can couple to the evanescent states and thus contribute to the conductance. Symmetry of the evanescent state with the smallest decay rate determines bands of the electrode that can most efficiently tunnel through the insulator. For ferromagnetic electrodes, at the Fermi energy the majority-spin bands may have symmetry different from that of the minority-spin bands, resulting in a different coupling to the evanescent states. These considerations allow conclusions about the SP of the conductance and the TMR in MTJs to be made.

4.1 Fe/MgO/Fe tunnel junctions

Let us consider epitaxial Fe/MgO/Fe(001) tunnel junctions as an example of the application of this method. We will see that symmetry arguments predict very large values of TMR in these junctions consistent with first-principles (Butler, Zhang, Schulthess and MacLaren, 2001) and tight-binding (Mathon and Umerski, 2001) calculations.

MgO, like many other insulators, has a direct band gap at the Γ point and for not too thin MgO barriers the dominant contribution to the conductance comes from electrons near the $\overline{\Gamma}$ point ($\mathbf{k}_{||} = 0$). Decay constants of the two relevant

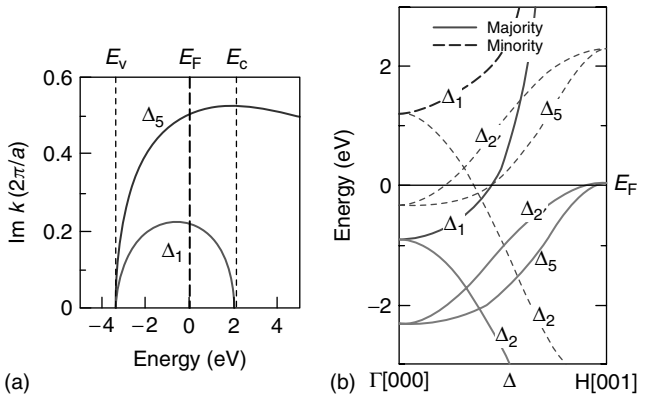

Figure 1. (a) Complex band structure of MgO at the $\overline{\Gamma}$ point. Two evanescent states which have lowest decay rates are shown. The position of the Fermi level, E_F, in a Fe/MgO/Fe MTJ and the top of the valence band, E_v, and the bottom of the conduction band, E_c, are displayed by dashed lines. (b) Spin- resolved band structure of Fe along the [001] direction. Bands are labeled by their symmetry representation. Thick lines mark the Δ_1 bands which match the symmetry of the evanescent state in MgO which has the lowest decay rate. (Courtesy of J.P. Velev.)

evanescent states with $\mathbf{k}_{||} = 0$ are shown in Figure 1(a) as a function of energy. We see that the state that has a minimum decay constant $\kappa_{\min}$ belongs to a Δ_1 symmetry (the identity representation). If any electron originating from the Fe electrode is to tunnel via this state, it must belong to a state in Fe that also belongs to Δ_1 symmetry, so that it can couple to the evanescent state. In the Fe electrode, the k-space direction Δ corresponding to the (001) surface is $\Gamma - H$. Looking at the band structure of Fe in this direction (Figure 1b), we see that the relevant band of symmetry Δ_1 at the Fermi energy appears *only* within the majority-spin channel. This band couples to the Δ_1 evanescent state in MgO and passes to the other side of the barrier. Electrons of other symmetries are cut off by a thick enough MgO barrier. For example, electrons of Δ_5 symmetry which appear at the Fermi energy of Fe both within the majority- and minority-spin channels (Figure 1b) are coupled to the evanescent state of Δ_5 symmetry which has larger decay constant (Figure 1a) and therefore decay faster in the barrier. This makes the SP of the conductance across Fe/MgO interface to be positive and close to 100% for sufficiently thick barriers. Therefore, when coupled to MgO barrier, Fe(001) behaves like a half-metal because it has the Δ_1 band contributing to the conductance only in the one spin channel.

When the electron has reached the interface of the second electrode, it will or will not be allowed to continue, depending on the relative magnetization orientation of the two electrodes. For the parallel orientation, it will couple efficiently to the majority Δ_1 state and continue. For the antiparallel orientation, however, majority-spin electrons tunnel to minority-spin bands which have no Δ_1 symmetry states at the Fermi energy. This implies that there is no conductance for the parallel configuration and hence infinitely large TMR. These arguments are exact for the state of $\kappa_{\min}$, at $\mathbf{k}_{||} = 0$, but for reasons of continuity they will almost hold for $\mathbf{k}_{||}$ near the $\overline{\Gamma}$ point. The presence of the spin-dependent electron reflection from MgO thin films grown on Fe(001) has recently been demonstrated experimentally using spin-polarized low-energy electron microscopy (Wu, Schmid and Qiu, 2006).

In addition to bcc Fe, other crystalline ferromagnetic metals such as bcc Co and bcc FeCo alloys have the Δ_1 symmetry band at the Fermi energy only within the majority-spin channel. Using the symmetry arguments discussed above, we can conclude that large values of TMR are expected for MTJs with these electrodes and MgO barriers if they are stacked in the (001) direction. This is confirmed by first-principles calculations (Zhang and Butler, 2004) and has recently been observed experimentally (Yuasa *et al.*, 2006). The considerations based on symmetry explain large values of TMR which are observed experimentally in crystalline MgO-based tunnel junctions (Faure-Vincent *et al.*, 2003; Parkin *et al.*, 2004; Yuasa *et al.*, 2004; Djayaprawira *et al.*, 2005; Hayakawa *et al.*, 2006).

In a broad class of insulating materials the states that belong to the identity representation have minimum decay rates. For semiconductors (insulators) with a direct band gap (such as GaAs, ZnSe, or semiconductors with a higher atomic number or/and ionicity) these states are centered on the Γ point. One would therefore expect a large TMR in epitaxial MTJs with these barriers and bcc Fe (Co, FeCo) if they stacked along the (001) direction. For example, a large TMR has been predicted for Fe/ZnSe/Fe(100) MTJs (MacLaren, Zhang, Butler and Wang, 1999). Unfortunately, experimentally epitaxial Fe/ZnSe/FeCo MTJs show much less impressive behavior compared to MgO-based MTJs demonstrating a sizable magnetoresistance of 16% only at low temperatures (Gustavsson, George, Etgens and Eddrief, 2001). This is a consequence of a semiconducting nature of the ZnSe barrier which makes the mechanism of conductance to be different from that considered theoretically. Owing to a smaller band gap the presence of impurity/defect states close to the Fermi energy makes the ballistic approach inadequate for the description of SDT in these junctions at such barrier thicknesses where according to the symmetry arguments the TMR should be large.

We note that the presence of disorder in the barrier layer may also produce notable effects on electronic transport in MgO-based tunnel junctions. Localized states in MgO have been observed using scanning tunneling spectroscopy measurements (Klaua *et al.*, 2001; Mather, Read and Buhrman, 2006). These states are attributed to O vacancies or other structural defects, arising because of nonideal

growth conditions. It is known that the mechanism of electron transport in such imperfect MTJs is very different compared to ideal junctions (Tsymbal and Pettifor, 1998), which may affect significantly the transport SP (Vedyayev, Bagrets, Bagrets and Dieny, 2001) and even lead to the reversal of TMR (Tsymbal, Sokolov, Sabirianov and Doudin, 2003). Recent first-principles calculations predict that O vacancies in MgO produce nonresonant scattering of tunneling electrons causing a reduction of TMR (Velev, Belashchenko, Jaswal and Tsymbal, 2007). For thicker barriers, tunneling mediated by O vacancies may explain the observed slope of the logarithm of resistance as a function of MgO thickness independent of the magnetization orientation (Yuasa *et al*., 2004). This behavior is inconsistent with direct tunneling, because in perfect Fe/MgO/Fe MTJs the decay lengths of the evanescent states controlling the conductance for parallel and antiparallel magnetizations are different (Butler, Zhang, Schulthess and MacLaren, 2001).

4.2 Co/$SrTiO_3$/Co tunnel junctions

A completely different behavior is predicted for perovskite barrier electrodes, such as $SrTiO_3$, in which the symmetry of the complex band structure of $SrTiO_3$ enables efficient tunneling of the minority d electrons from bcc Co, causing the SP of the conductance across the $SrTiO_3$interface to be negative (Velev *et al*., 2005). Using the structural model of an epitaxial Co/$SrTiO_3$/Co(001) MTJ (Oleinik, Tsymbal and Pettifor, 2002) a very large TMR was predicted for this junctions.

The fact that the tunneling current is dominated by minority-spin electrons can be explained by taking into account the band structure of bcc Co and decay rates of the Co states in $SrTiO_3$. The majority-spin 3d band in bcc Co is filled, so that the DOS at the Fermi level has a large negative SP (Bagayoko, Ziegler and Callaway, 1983). Actually, the band structure of bcc Co along the Δ direction is very similar to that of bcc Fe shown in Figure 1(b) with the Fermi energy shifted up by about 1 eV. Owing to the symmetry of the evanescent states with lowest decay rates in $SrTiO_3$ the 3d states could efficiently tunnel through the barrier. Indeed, as is seen from the complex band structure of $SrTiO_3$ shown in Figure 2(a) at the $\overline{\Gamma}$ point ($\mathbf{k}_{||} = 0$), the Δ_5 and Δ_1 states have comparable decay rates in the gap of $SrTiO_3$. Therefore, both the majority-spin Δ_1 band and the minority-spin Δ_5 band of bcc Co can tunnel efficiently through the $SrTiO_3$ barrier.

While the $\overline{\Gamma}$ point analysis is instructive, it is not sufficient in this case because the conductance is not dominated by this point. This fact can be understood from Figure 2(b), showing the three lowest decay rates of the evanescent states at the Fermi energy. It is seen that a very large area of the Brillouin zone, forming a cross pattern along the $\overline{\Gamma}$–M directions, exhibits two lowest decay rates that are very close to those at the $\overline{\Gamma}$ point. Clearly, at large barrier thickness the states lying in this 'cross' area should dominate the conductance. This feature is in sharp contrast to sp-bonded insulators like MgO and Al_2O_3 where the decay rate has a deep parabolic minimum in the vicinity of the $\overline{\Gamma}$ point. This difference is due to the conduction band of $SrTiO_3$, which is formed by fairly localized 3d states of Ti instead of free-electron-like states of a metal atom in simple oxides. Therefore, the minority-spin d states which have much larger DOS at the Fermi energy than the majority-spin states dominate the conductance providing a negative SP of the tunneling current in Co/$SrTiO_3$/Co MTJs. This finding is in agreement with the experimental observations of (De Teresa *et al*., 1999a,b), who found that the transport SP of the Co/$SrTiO_3$ interface is negative, opposite to that of the Co/Al_2O_3 interface.

5 INTERFACE RESONANT STATES AND INTERFACE BONDING

The presence of surface electronic states on a surface of a metal is well known. If these states are coupled to bulk Bloch states, they are called *surface resonant states* or *surface resonances*. For example, the presence of minority-spin resonant states on the Fe(001) surface is well established experimentally, for example, by STM measurements (Stroscio *et al*., 1995).

Interface resonances may appear in MTJs and influence their transport properties (Wunnicke *et al*., 2002). The minority-spin interface resonances are present at the Fe(001)/MgO interface, as was found from first-principle calculations (Butler, Zhang, Schulthess and MacLaren, 2001) and was indirectly observed in tunneling experiments (Tiusan *et al*., 2004, 2006). Within a two-dimensional Brillouin zone these resonant states represent a surface band sharply peaked near the Fermi energy. Calculations show that the interface Fe(001)/MgO band is very flat making it extremely sensitive to electron energy (Belashchenko, Velev and Tsymbal, 2005). This can be seen from Figure 3, which shows the density of electronic states resolved with respect to the transverse wave vector $\mathbf{k}_{||}$ for different energies. It is evident that a significant change in the location of these bands within the first Brillouin zone occurs when energy is shifted by a tiny amount of 0.02 eV.

The formation of interface resonant states is largely controlled by the atomic structure and bonding at the interface. This can already be seen within a simple tight-binding model (Tsymbal and Belashchenko, 2005) which shows that the interplay between the interface on-site atomic

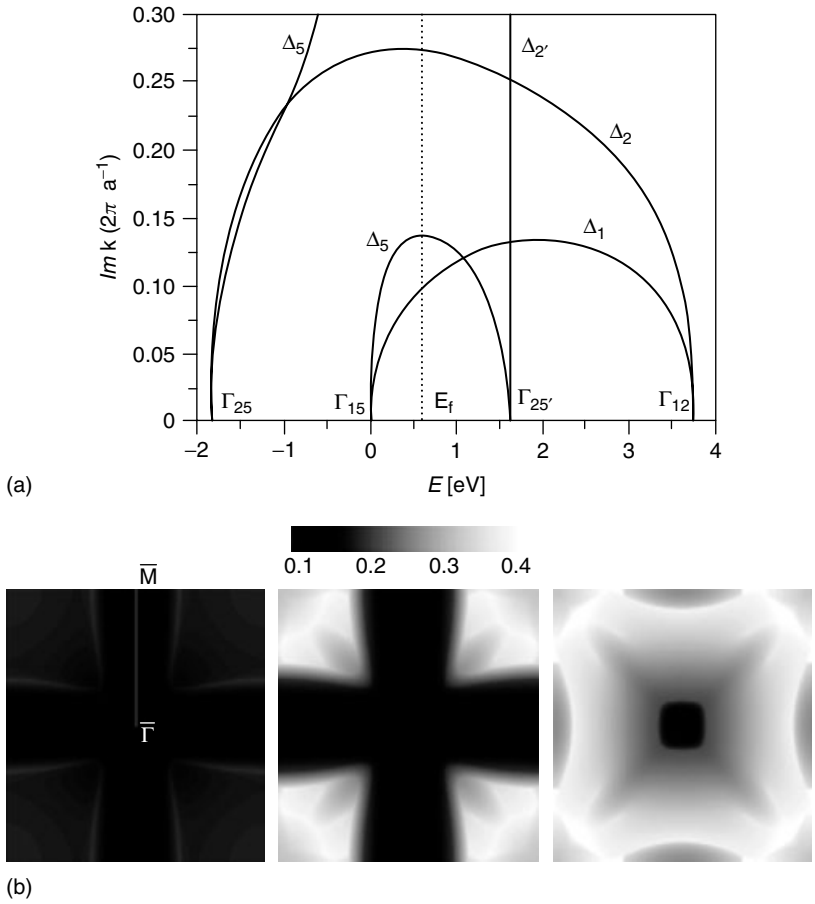

Figure 2. (a) Complex band structure of $SrTiO_3$ at the $\overline{\Gamma}$ point showing evanescent states which have lowest decay rates. The position of the Fermi level E_F in a Co/$SrTiO_3$/Co MTJ is indicated by a dashed line. (b) Three lowest decay rates (in units of $2\pi/a$) of the evanescent states in $SrTiO_3$ as a function of $\mathbf{k}_{||}$ at the Fermi energy. (Reproduced from J. Velev *et al*., 2005, with permission from the American Physical Society. © 2005.)

energies and the strength of interface bonding may result in the appearance of an interface resonance. The width of this resonance is controlled by its coupling to bulk states that is determined by the interface bonding and the interface potential.

Theoretically, interface resonant states can produce a very large tunneling current if they match identical resonances at the opposite interface (Wunnicke *et al*., 2002; Tusche *et al*., 2005). In practice, however, this situation is unlikely because the interface resonances are always mismatched by structural disorder, inelastic scattering and a small applied bias voltage (Velev, Belashchenko and Tsymbal, 2006). This is the consequence of the fact that the intrinsic damping of resonant states is very small as a result of their weak coupling to bulk states. Inelastic scattering and structural disorder broaden the resonant states thereby strongly reducing the conductance through this channel. A small applied bias voltage produces a similar effect due to a mismatch of resonances at the opposite interfaces. The detrimental effect of disorder is seen from calculations using realistic structure models (Xu *et al*., 2006; Mathon and Umerski, 2006).

The situation described above does not, however, diminish the role of interface resonant states and interface bonding in transport properties of MTJs. Actually, as was mentioned in the introduction, in many cases the interface atomic and electronic structure play a decisive role in spin transport. Below we consider three examples where interface bonding and interface resonant states control the SP of the tunneling current in MTJs.

5.1 Interface resonant states in Fe/MgO/Fe tunnel junctions

First, we consider epitaxial Fe/MgO/Fe(001) MTJs. As explained in Section 4.1 on the basis of symmetry arguments, these junctions should possess very large values of TMR for sufficiently thick MgO barriers. This is due to the

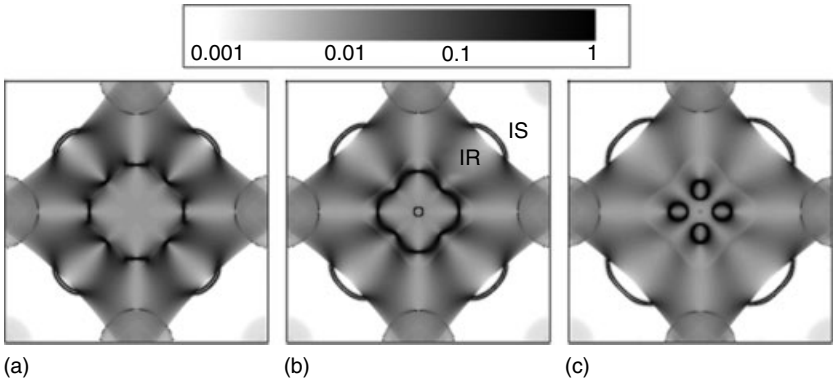

Figure 3. $\mathbf{k}_{||}$-resolved minority-spin density of states (in arb units) for Fe(001)/MgO interface calculated for three different energies near the Fermi energy (E_F): (a) $E = E_F - 0.02\,eV$, (b) $E = E_F$, (c) $E = E_F + 0.02\,eV$. Interface resonant states are denoted by IR. (Reproduced from K.D. Belashchenko *et al.*, 2005, with permission from the American Physical Society. © 2005.)

contribution from the Δ_1 band which is present at the $\overline{\Gamma}$ point only in the majority-spin channel of Fe at the Fermi energy. At small barrier thickness, however, the conductance is not dominated by the $\overline{\Gamma}$ point, and symmetry arguments are no longer valid. Calculations of Belashchenko, Velev and Tsymbal (2005) show that the contribution from the interface resonant states becomes appreciable at MgO thickness below six monolayers (MLs) which results in the decrease of TMR. This is consistent with the experimental results which show that TMR in Fe/MgO/Fe(001) MTJs drops down precipitously for barrier thickness below 1.5 nm (Yuasa *et al.*, 2004). The interface resonant states may also affect the bias-voltage dependence of TMR (Zhang *et al.*, 2004).

Figure 4(a–c) shows the spin-resolved conductance for the MTJ with four MLs of MgO for the parallel and antiparallel magnetization. The large contribution to the conductance near the $\overline{\Gamma}$ point (Figure 4a) is due to the matching of the majority Δ_1 band in Fe and the respective evanescent state in the MgO. The conductance for the minority-spin channel (Figure 4b) and the conductance for the antiparallel magnetization (Figure 4c) are strongly enhanced for certain $\mathbf{k}_{||}$ points in the Brillouin zone. The comparison to Figure 3(b) indicates that this is due to the contribution from a resonant interface band. The enhancement of the conductance is most pronounced for small barrier thickness, because the interface band lies away from the $\overline{\Gamma}$ point, and therefore the resonant contribution to the transmission decays faster with barrier thickness compared to the nonresonant contribution. The enhanced contribution of these interface resonances leads to the decrease of TMR at low barrier thickness. Indeed, on grounds explained above (Velev, Belashchenko and Tsymbal, 2006), the contribution from the minority-spin channel for the parallel magnetization should be disregarded. On the other hand, the interface resonances *do* contribute to the conductance in the antiparallel configuration, where they tunnel into majority-spin states of the other electrode. The latter have no fine structure in the Brillouin zone, and hence the conductance is weakly sensitive to a potential mismatch at the two interfaces that might occur in real junctions.

The contribution from the interface resonance can be suppressed and consequently, the TMR can be enhanced if a thin epitaxial Ag layer is deposited at the two Fe/MgO interfaces. It is known that an epitaxial Ag overlayer on Fe(001) surface notably modifies the electronic structure of the surface states (Vescovo *et al.*, 1995). If the minority-spin interface DOS is reduced by Ag, the antiparallel conductance will be suppressed. On the other hand, the majority-spin conductance should not be strongly affected due to almost perfect transmission through the Fe/Ag(001) interface (Stiles, 1996). This is indeed what is predicted by the theory (Belashchenko, Velev and Tsymbal, 2005).

Figure 4(d–f) shows the $\mathbf{k}_{||}$- and spin-resolved conductance of Fe/MgO/Fe junctions with Ag interlayers. Not unexpectedly, for parallel magnetization the conductance is weakly affected by the Ag interlayers, whereas for antiparallel magnetization the conductance changes dramatically. The most pronounced difference is the disappearance of the contribution from interface resonances that dominated the conductance of the Fe/MgO/Fe junction with no Ag interlayers (compare Figure 4c and f). This strong change occurs owing to the Fe–Ag hybridization which makes the interface resonant band more dispersive and removes the Fermi level crossing responsible for the highly conductive resonant states. The significant reduction of the conductance in the antiparallel configuration leads to a dramatic enhancement of the TMR. Thus, Ag interlayers practically eliminate the contribution from the interface resonances and enhance TMR for thin barriers.

The noble metal interlayer may also enhance the TMR because of quantum-well states formed within the interlayer

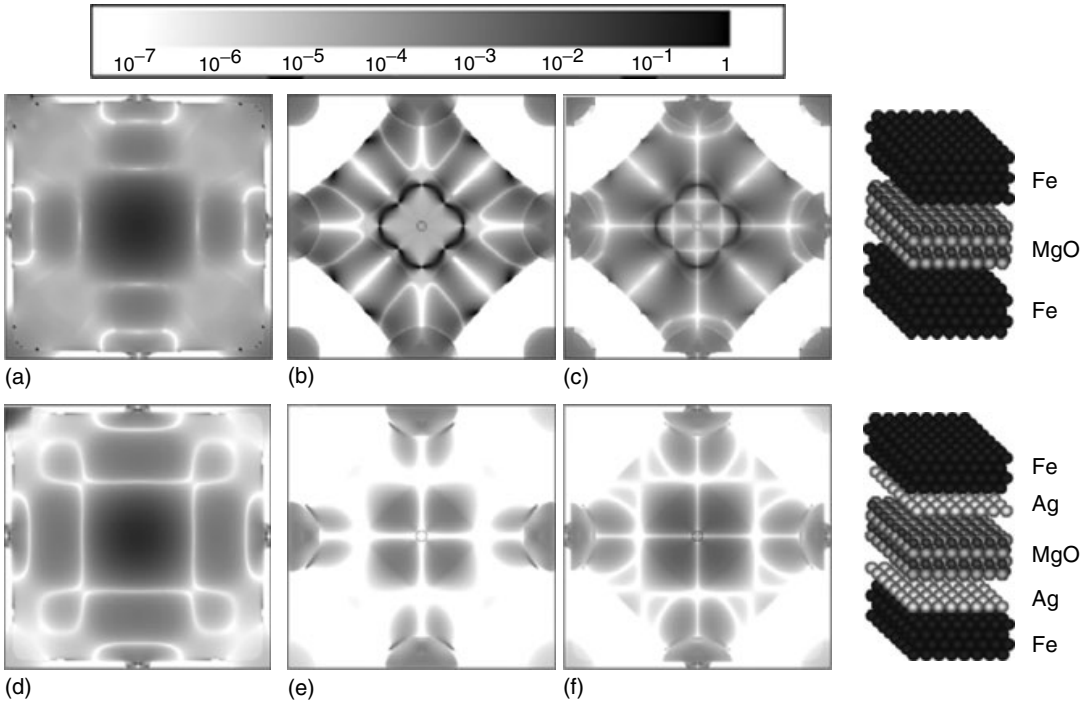

Figure 4. Conductance (in units of e^2/h) as a function of $\mathbf{k}_{||}$ for Fe/MgO/Fe (a, b, and c) and Fe/Ag/MgO/Ag/Fe (d, e, and f) tunnel junctions with four monolayers of MgO for majority spins (a), (d), minority spins (b), (e), each spin channel in the antiparallel configuration (c), (f). (Reproduced from K.D. Belashchenko *et al*., 2005, with permission from the American Physical Society. © 2005.)

(Mathon and Umerski, 2005). With increasing the interlayer thickness, a theory predicts an oscillatory dependence of TMR (Vedyayev *et al*., 1997; Mathon and Umerski, 1999) with a possibility of strong enhancement of the conductance and TMR at resonant conditions (Lu, Zhang and Pantelides, 2005) and tuning of quantum-well states by impurities (Kalitsov *et al*., 2004). Yuasa, Nagahama, and Suzuki (2002) found experimentally quantum-well oscillations in $Co/Cu/Al_2O_3/Ni_{80}Fe_{20}$ tunnel junctions with the bottom epitaxial Co/Cu(001) electrodes. Recently, quantum oscillations of the tunneling conductance in fully epitaxial double barrier Fe(001)/MgO/Fe/MgO/Fe MTJs were observed experimentally (Nozaki, Tezuka and Inomata, 2006) and calculated from first principles (Wang, Lu, Zhang and Han, 2006).

5.2 Tunneling from clean and oxidized Co surfaces through vacuum

Another interesting example that demonstrates the importance of interface states is tunneling from clean and oxidized Co surfaces through vacuum studied by Belashchenko *et al*. (2004). It shows the crucial role of bonding between Co and O atoms on the surface for SDT. This work investigates the SP of the tunneling current from a Co(111) electrode to a nonmagnetic Al(111) which serves as a detector of the tunneling SP in the spirit of the Tedrow–Meservey experiments.

Figure 5(a) and (b) show the $\mathbf{k}_{||}$-resolved conductance for the majority- and minority-spin electrons within the first surface Brillouin zone for a clean Co(111) surface. The Co Fermi surface viewed along the [111] direction has holes close to the $\overline{\Gamma}$ point with no bulk states in both spin channels, which results in zero conductance in this area. The majority-spin conductance (Figure 5a) varies rather smoothly and is appreciable over a relatively large area of the Brillouin zone. On the other hand, the minority-spin conductance (Figure 5b) has a narrow crown-shaped 'hot ring' around the edge of the Fermi surface hole. The analysis of layer and $\mathbf{k}_{||}$-resolved DOS shows that it is not associated with surface states, but rather with an enhancement of bulk $\mathbf{k}_{||}$-resolved DOS near the Fermi surface edge. As is seen from Figure 5(a) and (b), the Fermi surface hole is smaller for majority spins. Therefore, the conductance should become fully majority-spin polarized in the limit of very thick barriers. This occurs, however, only at barrier thickness $d \sim 10\,\text{nm}$, while for typical values of $d \sim 2\,\text{nm}$ the SP is about -60% and depends weakly on d.

An oxidized Co surface is modeled by placing an O monolayer on top of the Co(111) electrode such that O atoms lie in the threefold hollow-site positions above the subsurface Co layer (Figure 5f). The oxygen monolayer

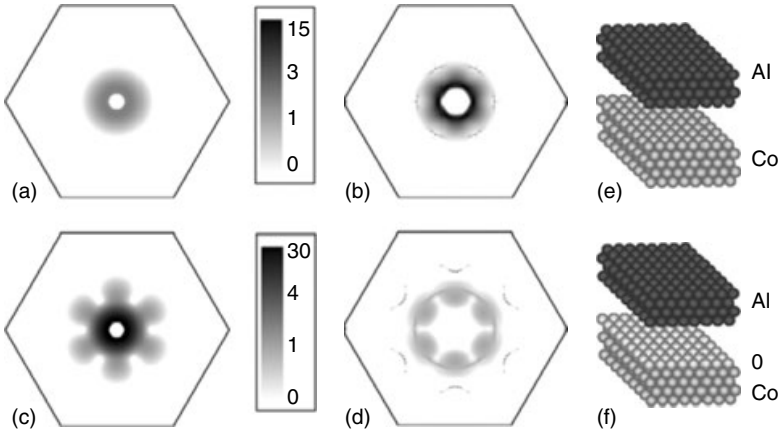

Figure 5. $\mathbf{k}_{||}$-resolved conductance (in units of e^2/h) from clean and oxidized (111) Co surfaces through vacuum into Al: (a) clean surface, majority spin; (b) clean surface, minority spin; (c) oxidized surface, majority spin; (d) oxidized surface, minority spin. Vacuum layer thickness is 2 nm for clean and 1.7 nm for oxidized Co surface. Units are $10^{-11}e^2/h$ for (a), (b) and $10^{-14}e^2/h$ for (c), (d). Geometry for clean and oxidized Co surfaces are shown in (e) and (f), respectively. (Reproduced from K.D. Belashchenko *et al*., 2004, with permission from the American Physical Society. © 2004.)

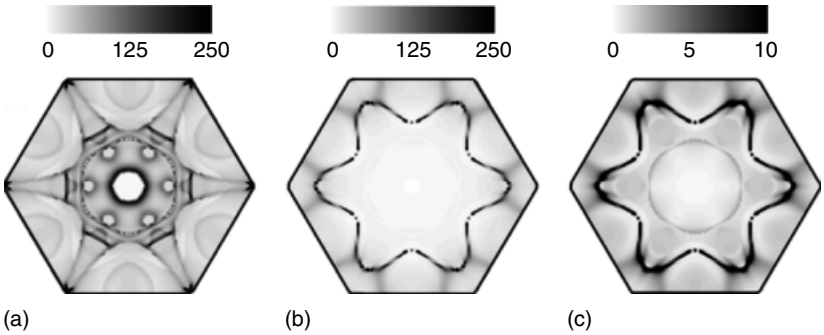

Figure 6. $\mathbf{k}_{||}$-resolved minority-spin local DOS (arb units) at the Fermi energy for the oxidized Co(111) surface: (a) bulk Co; (b) subsurface Co monolayer; (c) surface O monolayer. (Reproduced from K.D. Belashchenko *et al*., 2004, with permission from the American Physical Society. © 2004.)

dramatically changes the electronic structure reducing the magnetic moment of the underlying Co to 0.17 μ_B. Interestingly, the presence of the almost magnetically dead monolayer of Co at the interface does not kill the SP of the conductance; it rather changes sign of the SP from negative to positive. This fact is evident from Figure 5(c) and (d) which indicates that the overall reduction in the conductance due to oxidation is accompanied by the dominant suppression of the minority-spin transmission.

The origin of this behavior can be understood from Figure 6 which displays the $\mathbf{k}_{||}$- and layer-resolved minority-spin DOS at the Fermi energy. For bulk Co the Fermi surface edges are strongly emphasized in the DOS (Figure 6a). One of them representing a ring around the $\overline{\Gamma}$ point dominates the minority-spin conductance for the clean Co surface (compare to Figure 5b). The oxidation results in the strong covalent bonding between Co and O atoms at the surface producing an antibonding band which is clearly seen in the $\mathbf{k}_{||}$-resolved DOS for Co and O surface monolayers (Figure 6b and c). This resonant band appears only in the minority-spin channel and removes the spectral weight from the center of the Brillouin zone. As a result, the bulk minority-spin states responsible for most tunneling transmission from the clean surface encounter a band gap in the surface Co and O layers which is equivalent to adding an additional tunneling barrier. Thus, the tunneling conductance for the MTJ with the oxidized Co surface is fully dominated by the majority-spin channel, resulting in the SP of about +100%.

Experimentally, the reversal of the SP associated with surface oxidation may be detected using spin-polarized STM measurements (Bode, 2003). Since the ferromagnetic tip is sensitive to the SP of the total local DOS above the surface, the TMR in the system surface/vacuum/tip should change sign when Co surface is oxidized. In other words, for the clean Co(111) surface the tunneling current should be higher when the magnetizations of the tip and the surface are aligned

parallel, but for the oxidized surface it should be higher for the antiparallel alignment.

5.3 Role of interface Co–O bonding in $Co/Al_2O_3/Co$ tunnel junctions

Interface bonding plays a decisive role in SDT in $Co/Al_2O_3/Co$ MTJs as is shown by Belashchenko, Tsymbal, Oleinik and van Schilfgaarde (2005). Assuming crystalline epitaxy at the interface between fcc Co(111) electrodes and an Al_2O_3 barrier this work considers two fully-relaxed atomic configurations of the O-terminated interface that differ only by the presence or absence of an adsorbed oxygen atom at the interface (Figure 7). Model 1 (Figure 7a and b) represents the O-terminated $Co/Al_2O_3/Co$ structure with three oxygen atoms per unit cell (Oleinik, Tsymbal and Pettifor, 2000). These oxygen atoms participate in bonding with the two adjacent Al atoms, making the bonds of the latter fully saturated. Model 2 (Figure 7c and d) adds an additional O atom in the threefold hollow site. This O atom and the neighboring Co atoms are labeled 'II' in Figure 7(c) and (d), whereas the other O and surface Co atoms are labeled 'I'. Structural sites occupied by O(I) and O(II) atoms are very dissimilar. O(II) atoms lie much closer to the Co surface compared to O(I) atoms and, hence, are more strongly coupled to Co than O(I) atoms.

This distinction is evident in the local DOS for the interfacial atoms shown in Figure 8. Similar to the Co(111) surface with an adsorbed oxygen monolayer, Co(II) and O(II) atoms in model 2 form bonding and antibonding orbitals which are clearly seen in the local DOS plots. The bonding states lie below the bottom of the Co 3d band, while the antibonding states are slightly above the Fermi level. While the magnetic moment of Co(II) atoms is notably reduced ($1.30\,\mu_B$), this effect is much smaller compared to the oxidized Co surface, because in model 2 there is only one 'adsorbed' O(II) atom per three Co(II) atoms. The local DOS for Co(I) atoms remains quite similar to bulk Co, while the local DOS for O(I) atoms shows a small but notable 'echo' of the Co(II)–O(II) antibonding states.

The spin asymmetry of the conductance for these tunnel junctions can be analyzed by calculating the spin-resolved conductance per unit cell area for the parallel orientation of electrodes. Model 1 shows that the majority-spin conductance $G_{\uparrow\uparrow} = 0.0042e^2/h$ is smaller than the minority-spin conductance $G_{\downarrow\downarrow} = 0.023e^2/h$. This implies that the SP $P = \left(G_{\uparrow\uparrow} - G_{\downarrow\downarrow}\right) / \left(G_{\uparrow\uparrow} + G_{\downarrow\downarrow}\right)$ is negative and equals -70%. Note that, although this quantity is not directly measurable, it correlates with the measurable SP. This situation changes dramatically when an additional O atom is placed at the interface. The model 2 exhibits a reversal of the SP from negative to positive. The total conductances per cell area are $G_{\uparrow\uparrow} = 0.087e^2/h$ and $G_{\downarrow\downarrow} = 0.045e^2/h$, and the $P = +32\%$.

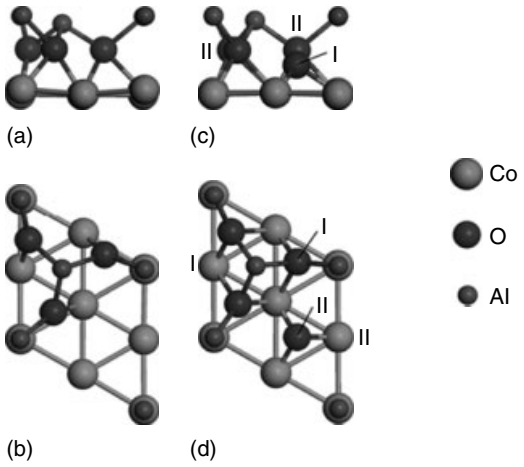

Figure 7. Interface structure of the $Co/Al_2O_3/Co$ MTJ for model 1 (a, b) and model 2 (c, d). (a) and (c) 'Front' views from a direction normal to the threefold axis. (b) and (d) 'Top' views along the threefold axis. There are two types of Co and O atoms at the interface for model 2: three O(I) atoms, one O(II) atom, one Co(I) atom, and three Co(II) atoms per unit cell. (Reproduced from K.D. Belashchenko *et al*., 2005, with permission from the American Physical Society. © 2005.)

Thus, we see that the strong interface bonding with O atoms is responsible for the positive SP of the tunneling current in $Co/Al_2O_3/Co$ tunnel junctions. This bonding produces antibonding Co–O states that are present at the Fermi level in the majority-spin channel. These interface states moderately mix with the bulk states, forming interface resonances, which strongly assist tunneling. On the other hand, the minority-spin antibonding Co–O states lie above the Fermi energy because of exchange splitting and do not affect the conductance.

These results suggest that the common argument of the dominant s-electron contribution to tunneling, which is often used to explain the positive SP of the alumina-based tunnel junctions is not justified. The strong interfacial bonding between Co and O atoms at the interface may be the major factor resulting in the positive SP as is observed in experiment.

6 CONCLUSIONS

It was believed for a long time that the tunneling SP in MTJs is solely determined by the electronic and magnetic properties of ferromagnetic electrodes (such as the total DOS or the DOS of itinerant bands the at the Fermi energy). This idea was, in particular, based on the agreement between measured values of the SP of the tunneling

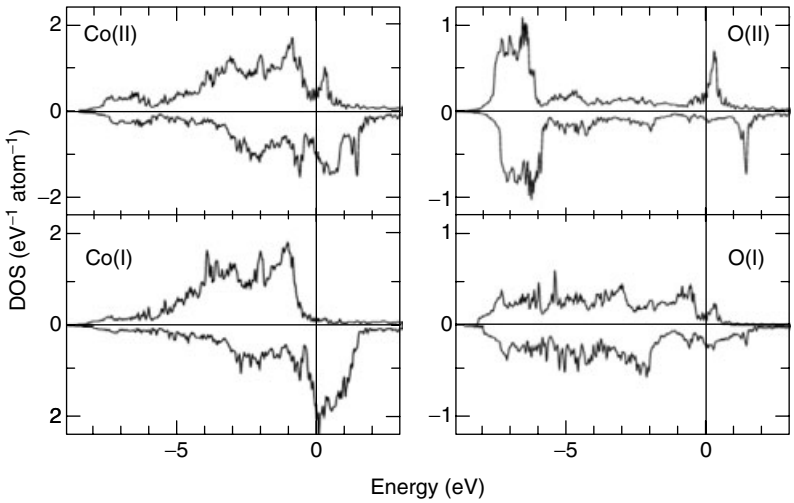

Figure 8. Local DOS per atom for interfacial atoms in model 2. In each panel, top half shows the majority-spin DOS, and bottom half, the minority-spin DOS per atom. The vertical line denotes the position of the Fermi level. (Reproduced from K.D. Belashchenko *et al*., 2005, with permission from the American Physical Society. © 2005.)

current across Al_2O_3 barriers using the Tedrow–Meservey technique and the maximum TMR values reported for Al_2O_3 barriers within Jullière's model. However, later it became clear that not only the electronic structure of ferromagnets but also the electronic structure of the ferromagnet/insulator interface and the evanescent states in the insulator control the tunneling SP. It is now commonly accepted that the SP entering the Jullière's formula is due to the ferromagnet/barrier complex rather than the ferromagnet alone. Theoretically, this concept can be explained in terms of the interface transmission function (Belashchenko *et al*., 2004), which explains the essence of the effective tunneling DOS used in the Jullière's formula.

We have considered a few examples that illustrate the role of evanescent states in the insulating barrier and bonding at the ferromagnet/barrier interface in controlling the SP of the tunneling current in epitaxial tunnel junctions (MTJs). Symmetry of the evanescent states selects spin-polarized bands in the ferromagnetic electrodes that are able to efficiently tunnel through the barrier. In particular, the matching of the majority-spin Δ_1 band in ferromagnetic Fe(001) to the Δ_1 complex band in MgO which has the lowest decay rate at the Fermi energy and the absence of the minority-spin Δ_1 band at the Fermi energy in bulk Fe are responsible for large values of TMR observed in crystalline Fe/MgO/Fe and similar junctions.

The complex band structure of $SrTiO_3$ explains a large negative tunneling SP in bcc $Co/SrTiO_3/Co(001)$ MTJs. This is the consequence of the localized 3d states of Ti, which contribute to the band structure of $SrTiO_3$ and allow efficient tunneling of minority d electrons of Co that have a large weight at the Fermi energy. This behavior is a drastic departure from the mechanism of tunneling in MTJs based on sp-bonded insulators such as Al_2O_3 and explains the experimental observation of the negative SP of electrons tunneling from Co through $SrTiO_3$ (De Teresa *et al*., 1999a,b).

The interface bonding may result in the appearance of interfaces resonant states which dramatically affect the SP of the tunneling current. These states are responsible for a decrease of TMR in Fe/MgO/Fe(001) MTJs for small barrier thickness. A monolayer of Ag epitaxially deposited at the interface between Fe and MgO suppresses tunneling through the interface band and may thus be used to enhance the TMR in these junctions.

The SP of the tunneling current from Co(111) through vacuum is predicted to be negative but can be reversed by deposition of a monolayer of oxygen on the Co(111) surface which makes the SP close to +100%. This effect occurs owing to the formation of surface bands that mix well with bulk majority-spin states but create an additional tunneling barrier for minority-spin states. This phenomenon could be observed using STM measurements.

The strong interface bonding between Co and O atoms at the interface in $Co/Al_2O_3/Co$ MTJs explains positive values of the SP observed experimentally. These results show that the common argument suggesting that s electrons dominate tunneling, which is often used to explain positive SPs observed experimentally in Al_2O_3-based tunnel junctions is quantitatively incorrect. In reality, the SP in these junctions is controlled by the interfacial structure and bonding. The strong interface bonding between a ferromagnetic atom and O is likely responsible for the positive SP in these junctions.

The sensitivity of the tunneling SP and TMR to the interface atomic and electronic structure expands the possibilities for engineering optimal MTJ properties for device applications.

1 INTRODUCTION

The continuing technological demand for high sensitivity, fast, and inexpensive magnetic macro and nanosensors for use in a number of applications including ultrahigh-density magnetic recording (Childress and Fontaua, 2005), medical instrumentation (Rinck, 1993), consumer electronics (Fraden, 1993), machine tool positioning (Kuze and Shibasaki, 1997), and for rotation and speed sensing in vehicles (Heremans, 1997), has, during the past two decades, stimulated an extensive worldwide research effort to improve the properties of magnetic sensors in general and magnetic nanosensors in particular. The natural focus of this research has been on materials and material structures that exhibit significant magnetoresistance (MR) at room temperature.

Two classes of fundamental physical phenomena that give rise to MR have received the overwhelming bulk of this research attention. One which is based on spintronic effects associated with the perturbation to the interfacial spin-dependent scattering cross section (Dieny, 1994) by the applied magnetic field, usually in layered structures composed of ferromagnetic metals, nonmagnetic metals and/or nonmagnetic insulators, gives rise to the well-known giant magnetoresistance (GMR) (Egelhoff, 1995) and tunneling magnetoresistance (TMR) (Mitra *et al*., 2001) effects that have been addressed elsewhere in this volume. The other which is based on the change in resistance associated with a bulk magnetic phase transition is responsible for the colossal magnetoresistance (CMR) (Rao and Raveau, 1998) effect. While GMR has had huge technological impact in the form of read-head sensors in modern computer hard disk drives (Daughton and Chen, 1993) and TMR represents the next generation read-head device (Song *et al*., 2000), CMR has and is unlikely to have a concomitant effect because it requires relatively low temperatures and high magnetic fields to exhibit acceptable sensing properties (Rao and Raveau, 1998).

The high sensitivity of magnetic devices exhibiting GMR, TMR, and CMR is based on the physical or intrinsic contributions to the MR (Popovic, 1991). Such physical contributions involve the dependence of carrier mobility, energy-band structure, spin−spin interactions and carrier concentration on the applied magnetic field. However, the magnetotransport property of any physical object also depends on a geometric contribution (Popovic, 1991). These geometric contributions depend on the shape of the device, the location of the contacts, and the location, shape, and relative conductivity of any macroscopic or nanoscopic inhomogeneities that might be present in the device structure. For most of the familiar MR devices such as those based on GMR, TMR or CMR, it is the physical contribution that dominates the

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

transport properties. Nevertheless, it has been recently shown that by judicious design of simple structures, the geometric contribution can be made to play an important, indeed even dominant role (Lee, Wingreen, Solin and Wolff, 1994; Lee, Solin and Hines, 1993; Thio and Solin, 1998; Thio *et al*., 1998a,b; Solin, Thio, Hines and Heremans, 2000). An example of the former is the phenomenon of ballistic magnetoresistance (BMR) while an example of the latter is extraordinary magnetoresistance (EMR). It is these two unconventional phenomena that we address in this chapter. To facilitate an in-depth discussion of EMR and BMR it is useful to illustrate the impact of geometry on magnetotransport with a succinct example.

To establish the magnetotransport properties of a material it is usual to perform a measurement of the Hall effect (Seeger, 1985; Popovic, 1991) by fabricating a Hall bar structure from (what is assumed to be) homogeneous material as indicated in Figure 1(a). Here, a bias current is applied along the x axis, the Hall voltage is measured along the y axis and the magnetic field is applied along the z axis (e.g., into the plane of the figure). One can also employ the Hall bar to measure the MR along the x axis. Now assume that the material being measured has one dominant carrier, say electrons whose mobility is typically much larger than that of holes (Zawadzki, 1974), and assume that these carriers have a δ-function velocity distribution, for example, they all move with the same velocity, the drift velocity. On application of a magnetic field, there will be a transient period during which the electrons are deflected, by the Lorentz force, to one side of the Hall bar. Eventually, a steady state excess of electrons will accumulate on one side of the Hall bar to form a negative space charge. This space charge generates a Hall field as indicated in Figure 1(a), and the force on the carriers from the Hall field just counter balances the Lorentz force. Thus, after the short transient during which the space charge is developed, there is no net force in the y direction and the current flows unperturbed along the x axis. Then, no current flows in the y direction and the x current is independent of the magnetic field. In this case, the MR $\Delta\rho(H)/\rho_0 \equiv [\rho(H) - \rho_0]/\rho_0 \equiv 0$, where H is the applied field, $\rho(H)$ is the field-dependent resistivity, and $\rho_0 = \rho(H = 0)$.

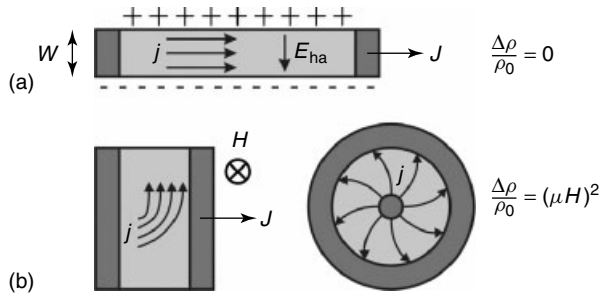

Figure 1. (a) A schematic representation of a Hall bar with the semiconductor region in dark gray and the metallic contacts in light gray. The current density, magnetic field are represented by J, H, and E_{ha}, respectively. For the conduction model discussed in the text, the magnetoresistance of this structure measured along the long axis is identically zero. (b) A schematic representation of a Corbino disk structure. For the conduction model discussed in the text, the magnetoresistance of this structure is $(\mu H)^2$ where μ is the carrier mobility.

Now consider the measurement configuration shown in Figure 1(b). Here the same material employed in Figure 1(a) is arranged in a so-called Corbino disk (Kleinman and Schawlow, 1960) with a cylindrical inner electrode and a concentric outer electrode between which is embedded the material to be measured. Current flows from the inner to the outer electrode or vice versa and the magnetic field is applied normal to the plane of the disk. Since the outer electrode is an equipotential, no asymmetric space charge can build up on its surface. Therefore, no Hall field develops to quench the effect of the Lorentz force on the carriers, which now follow a curved path to the outer electrode. The larger the applied field, the longer is this path and the higher is the field-dependent resistance of the disk. In this case, the MR is given by $\Delta\rho/\rho_0 = \mu^2 H^2$ where μ is the dominant carrier mobility (Popovic, 1991). The MR of the Corbino disk structure can be quite large, depending on the magnitudes of μ and H.

Obviously, the only difference between the measurements depicted in Figures 1(a) and (b) is in the geometry of the contact configurations since the intrinsic material properties are the same for both measurements. Moreover, for a homogeneous material with a two-contact configuration, it can be shown using the Onsager relations (Streater, 1999) that the maximum MR is obtained with a Corbino disk or its topological equivalent (Thio *et al*., 1998), for example, an electrode within an electrode but not constrained to cylindrical symmetry. Now that we have illustrated the general impact of geometry on magnetotransport, we will address specific examples in the following discussions of EMR and BMR.

2 EXTRAORDINARY MAGNETORESISTANCE

2.1 Background

During the course of their attempted study of a one-dimensional Mott transition in GaAs/$Ga_{1-x}Al_xAs$ superlattices, Solin and coworkers observed a room-temperature MR that was quadratic in the magnetic field, similar to that of a Corbino disk but much larger, and characterized the effect as GMR despite the fact that the system was

composed of nonmagnetic materials (Solin and Lee, 1995). Indeed, the effect was also larger than the GMR that is normally associated with ferromagnetic/metallic multilayers. Realizing that if the material in the Corbino structure was inhomogeneous and/or contained more than two contacts, then the 'Corbino maximum' MR could be exceeded, they quantitatively accounted for their observations by attributing the GMR to Corbino-like regions associated with interface fluctuations in the superlattice structure but with three or more isolated contacts on the outer edge of the disk.

Reasoning that for a given H, maximal MR is achieved with a material of maximum μ because, for semiconductors, μ is inversely proportional to carrier effective mass, m*, and m* is proportional to the energy gap, Solin, Thio and Hines (2000) concluded that narrow-gap materials were attractive candidates for nonmagnetic MR devices (Solin *et al*., 1999). They therefore launched a series of studies (Thio and Solin, 1998; Thio *et al*., 1998a,b) of $Hg_{1-x}Cd_xTe$ a material with an x-dependant gap that could be tuned through zero (Dornhaus and Nimtz, 1976). This nonmagnetic material also exhibited GMR (Thio and Solin, 1998; Thio *et al*., 1998a,b) which was associated with the presence of phase separated Hg precipitates that acted as metallic inhomogeneities but in a symmetric four-contact van der Pauw disc configuration (Wolfe, Stillman and Rossi, 1972) such as that shown in the inset of Figure 2. Clearly, it was much more desirable to control the shape and properties of the metallic inhomogeneity by lithographic patterning than to rely on nature. Accordingly, Solin *et al*. focused on InSb, a high-mobility narrow-gap semiconductor, which when patterned into vdP disks with concentric metallic inhomogeneities yielded such a large room-temperature MR (Solin, Thio, Hines and Heremans, 2000) that it was dubbed EMR (Solin *et al*., 2002a).

2.2 EMR in internally shunted circular macroscopic structures – experimental results

The proof of principal demonstration of EMR was accomplished with symmetric four-probe macroscopic vdP disc structures such as the one depicted in Figure 2 inset. Structures of this type are referred to as metal–semiconductor hybrids (MSH). The centered vdP disks which had an outer radius of 1 mm were prepared from metal organic vapor phase epitaxy (MOVPE) grown epilayers of Te-doped n-type InSb (Solin, Thio, Hines and Heremans, 2000). A buffer layer of 200 nm undoped InSb was grown on a 4 in semi-insulating GaAs substrate (resistivity $>1 \times 10^{17}\,\Omega\,\mathrm{cm}$). A 1.3 µm active layer of InSb (concentration $n = 2.11 \times 10^{16}\,\mathrm{cm}^{-3}$and mobility $\mu = 40\,200\,\mathrm{cm}^2\,\mathrm{Vs}^{-1}$) was deposited on the buffer layer and capped by a 50-nm InSb contacting

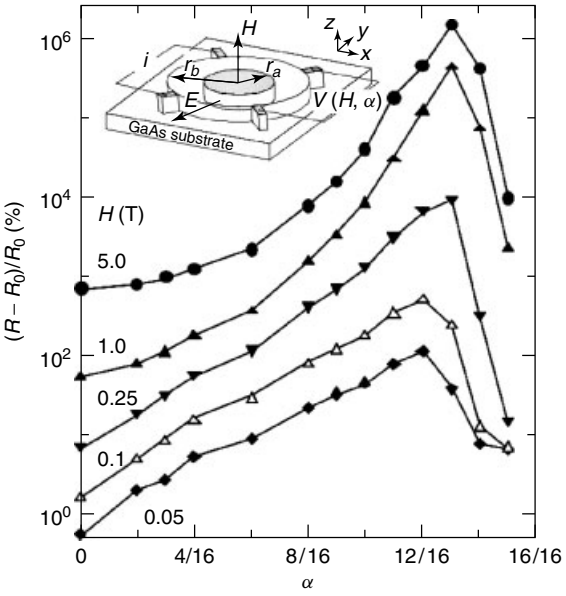

Figure 2. The field dependence of the magnetoresistance, $(R - R_0)/R_0$, of a Te-doped InSb van der Pauw disk of radius r_b in which is embedded a concentric right circular cylinder of Au of radius r_a. The filling factor is $a = r_a/r_b$. Inset: a schematic diagram of the hybrid disk structure. (Reprinted with permission Solin *et al*., copyright 2000, AAAS.)

layer ($n \sim 1.5 \times 10^{17}\,\mathrm{cm}^{-3}$). This epitaxial sequence was passivated by a 200 nm layer of Si_3N_4. The wafers were photolithographically patterned into chips bearing mesas for the vdP disks. The internal circular shunt embedded in the disk, together with the mesa contact pads were simultaneously metallized with a Ti/Pt/Au stack, with Au the dominant component. Additional details of the sample preparation and measurement are given elsewhere (Solin and Zhou, 2001).

Solin *et al*. also showed that in general,

$$EMR\,(\Delta H, H_{\mathrm{bias}}) = \frac{R^{\mathrm{eff}}\,(\Delta H + H_{\mathrm{bias}}) - R^{\mathrm{eff}}\,(H_{\mathrm{bias}})}{R^{\mathrm{eff}}\,(H_{\mathrm{bias}})} \quad (1)$$

where ΔH is the applied (signal) field normal to the plane of the device, $R^{\mathrm{eff}}(H)$ is the effective field-dependent resistance measured in a four-probe configuration, H_{bias} is the bias field and ΔH is the applied or signal field (not the field gradient; Solin, 2005). For small signals

$$EMR\,(\Delta H \to 0, H_{\mathrm{bias}}) = \left[\frac{1}{R^{\mathrm{eff}}\,(H_{\mathrm{bias}})}\right] \times \left[\frac{\mathrm{d}R^{\mathrm{eff}}(H)}{\mathrm{d}H}\right]_{H_{\mathrm{bias}}} \Delta H \quad (2)$$

where $\left[\mathrm{d}R^{\mathrm{eff}}\,(H)\,/\mathrm{d}H\right]_{H_{\mathrm{bias}}}$ is the current sensitivity. In the zero bias large signal but still low field limit, $\mu\Delta H \ll 1$, the EMR can be defined relative to either the zero-field resistance

or to the minimum resistance, the latter definition yielding the larger value which is comparable to the usual definition of MR adopted by the GMR community (Levy, 1994). Thus,

$$EMR(\Delta H) = \frac{R^{\text{eff}}(\Delta H) - R_j^{\text{eff}}}{R_j^{\text{eff}}} = G_j^{\text{S}}(\Delta H)\,[\mu \Delta H]^2 + G_j^{\text{AS}}(\Delta H)\,[\mu \Delta H] \quad j = 0, \min \tag{3}$$

Here $G_j^{\text{S}}(\Delta H)$ and $G_j^{\text{AS}}(\Delta H)$ are, respectively, symmetric and antisymmetric geometric factors which depend on the shape, location, and physical properties of the conducting inhomogeneity and contacts. (For the symmetric structure shown in the inset of Figure 2, $G_{\text{AS}}(\Delta H) = 0$.) Clearly, narrow-gap high-mobility semiconductors such as InSb and InAs are choice materials for EMR devices (Madelung, 1991).

The room-temperature magnetotransport properties of the macroscopic vdP structure shown in the inset of Figure 2 are shown in the main panel of Figure 2 as a function of the radius ratio $\alpha = r_a/r_b$, where r_a is the variable radius of a cylindrical embedded Au inhomogeneity and r_b is the fixed radius of the bulk thin film Te-doped InSb matrix. As can be seen from Figure 2, the room-temperature EMR is of order 10^6% at an applied field of 5 T. More importantly, the EMR exceeds 100% at the low field of 0.05 T. Values as high as 600% at 0.05 T have been achieved with galvanomagnetically equivalent externally shunted rectangular vdP plate structures (Zhou, Solin and Hines, 2000).

The EMR phenomenon can be readily understood using a simple though nonintuitive classical physics analysis based on diffusive transport (Seeger, 1985). The magnetoconductivity tensor for the semiconductor in the axial configuration shown in the inset of Figure 2 is

$$\sigma\,(H) = \begin{bmatrix} \dfrac{\sigma}{1+\beta^2} & \dfrac{-\sigma\beta}{1+\beta^2} & 0 \\ \dfrac{+\sigma\beta}{1+\beta^2} & \dfrac{\sigma}{1+\beta^2} & 0 \\ 0 & 0 & \sigma \end{bmatrix} \tag{4}$$

with σ being the dc conductivity and $\beta = \mu H$. If the electric field on the vertical surface of the inhomogeneity is $\vec{E} = E_x\hat{x} + E_y\hat{y}$, the current density is $\vec{J} = \underline{\sigma\,(H)}\vec{E}$. The electric field is everywhere normal to the equipotential surface of a highly conducting inhomogeneity. At $H = 0$, $\underline{\sigma\,(H)}$ is diagonal so $\vec{J} = \sigma\vec{E}$ and the current flows into the inhomogeneity which acts as a short circuit. At high $H(\beta > 1)$, the off-diagonal components of $\underline{\sigma\,(H)}$ dominate so $\vec{J} = (\sigma/\beta)\left[E_y\hat{x} - E_x\hat{y}\right]$ and $\vec{J} \perp \vec{E}$. Equivalently, the Hall angle (Popovic, 1991) between the electric field and the current density approaches 90°, and the current becomes tangent to, that is, deflected around, the inhomogeneity. Thus, the inhomogeneity acts as an *open circuit*. The transition of the inhomogeneity from short circuit at low H to open circuit at high H results in a geometric enhancement of the MR of the semiconductor even if its resistivity (conductivity) is field-independent (i.e., the physical MR is zero).

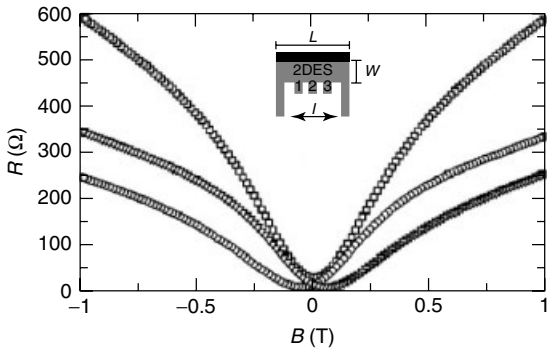

Figure 3. Resistance of an EMR van der Pauw plate device with W 520 mm at 4.2 K before illumination to increase carrier density by the persistent photo effect. (□) represents the data set of the symmetric configuration $R_{1,3}$. −(▽) and (○) symbolize the asymmetric ones, $R_{2,3}$ and $R_{1,2}$, respectively. Inset: a schematic diagram of the EMR device with the semiconductor in gray and the metal in black. (Reprinted with permission Moeller *et al*., copyright 2002, American Institute of Physics.)

Following the demonstration of EMR in macroscopic InSb–Au MSHs, Grundler and coworkers demonstrated low temperature (4.2 K) EMR in microscopic MSHs with dimensions of order 100 µm constructed from an InAs/InGaAs two-dimensional electron gas (2DEG) contacted by Au electrodes and a Au shunt (Moeller *et al*., 2002). This choice of materials provided an extremely low specific contact resistance of $10^{-8}\,\Omega\,\text{cm}^2$ which is important for technological applications. The results of Grundler and coworkers are shown in Figure 3 which depicts the field dependence of the resistance of their devices which were rectangular analogues of off-centered vdP disks (see further discussion in the subsequent text). They achieved an EMR as high as 115 000% at a field of 1 T (Moeller *et al*., 2002). In addition, they showed that the transport properties of low temperature EMR devices based on a 2DEG could be tailored for applications by manipulating the carrier mobility, density, and the geometry of the device. Moreover, they confirmed that EMR was due to current reallocation as outlined in the model proposed by Solin, Thio, Hines and Heremans (2000).

2.3 EMR in circular macroscopic structures – theoretical analysis

The centered vdP structure shown in the inset of Figure 2 was selected, in part, because its high symmetry allows one to readily obtain an analytic solution for the electric field

and current distribution by solving the Laplacian boundary value problem (Zhou, Solin and Hines, 2000). Indeed, this same construct and the analytic solution was first employed by Wolfe, Stillman and Rossi (1972) to explain the unusually large mobility exhibited by inhomogeneous GaAs. A similar approach was used by Solin *et al*. to analytically calculate the magnetotransport properties of the centered vdP disks with a series of discrete but increasing geometric factors with $0 \leq \alpha \leq 15/16$ (Zhou, Hines and Solin, 2001).

In Figure 4(a) is shown the room-temperature field dependence of the resistance of a series of InSb–Au vdP disks of the type and measuring configuration shown in the inset of Figure 2. This is the raw data from which the curves shown in Figure 2 were deduced. The corresponding plots shown in Figure 4(b) were obtained from the above-described solution to the Laplacian boundary value problem *with no adjustable parameters* (Zhou, Hines and Solin, 2001; Wolfe, Stillman and Rossi, 1972). As can be seen by comparing Figures 4(a) and (b), the calculated curves are in quantitative agreement with the measurements with one notable exception. The curve for $\alpha = 0$, for example, for the response of an un-shunted semiconductor shows a small MR effect as evidenced by the concave curvature near $\mathrm{H} = 0$ whereas the calculated curve for $\alpha = 0$ is flat. The origin of this discrepancy is the fact that the small MR for $\alpha = 0$ is due to the physical contribution which has not been including in the analytic calculation. This also highlights the clear dominance of the geometric contribution at higher values of α.

An alternate and more versatile approach to the calculation of the magnetotransport properties of EMR structures is the finite element method (FEM) (Ram-Mohan, 2002). The coauthors and their colleagues have shown that FEM is the ideal approach to modeling EMR since it can account for the spatially varying properties of arbitrarily shaped hybrid structures (Moussa *et al*., 2001). This method can also accommodate every type of boundary condition at interfaces and at boundaries/edges. In this case, the governing relation is the constitutive relation between the current and the field: $j_i = \sigma_{ij}(H)E_j$. With $E_i = -\partial_i \phi$, the current continuity condition takes the form $\partial_i \left(\sigma_{ij}\partial_j \phi(x, y)\right) = 0$. This partial differential equation has been solved using the FEM (Moussa *et al*., 2001) together with an approach based on the principle of least action (Zienkiewicz and Taylor, 1994; Hughes, 1987). In the EMR case, the action integral is given by

$$A = \frac{1}{2}\iint \mathrm{d}x\,\mathrm{d}y\,(\partial_i \phi(x, y))\sigma_{ij}(\partial_j \phi(x, y)) + \int_{\Delta_1} \mathrm{d}l\left[\phi(x, y)\right]|_{\Delta_1} j_{\mathrm{in}} - \int_{\Delta_2} \mathrm{d}l\left[\phi(x, y)\right]|_{\Delta_2} j_{\mathrm{out}} \quad (5)$$

where the current boundary conditions at the leads are easily incorporated into the calculations. The action is defined with an integral over time of the Lagrangian. Here the system is represented in the steady state. Consequently, the integral over time is suppressed for convenience. The double integral in equation (5) is just the electrostatic energy in the system. The presence of the field-dependent conductivity tensor poses no issue. In the FEM, the physical region is subdivided into triangles and action is evaluated in each triangle by representing the potential in terms of interpolation polynomials multiplied by unknown coefficients. On integrating the spatial dependence, the action is expressed as a binomial in the nodal coefficients with

$$A = \frac{1}{2}\phi_\alpha M_{\alpha\beta}\phi_\beta + \int_{\Delta_1} \mathrm{d}l\left[\phi(x, y)\right]|_{\Delta_1} j_{\mathrm{in}} - \int_{\Delta_2} \mathrm{d}l\left[\phi(x, y)\right]|_{\Delta_2} j_{\mathrm{out}} \quad (6)$$

The variational principle then leads to a matrix equation representing the discretized differential equation. This is solved for the unknown nodal values of the potential function. With no adjustable parameters, using the standard inputs for the conductivity of Au and InSb in the FEM calculations, excellent agreement is obtained between the experimental magnetotransport (or EMR) and its theoretically predicted values, as shown in Figure 4(c). The field-dependent current flow patterns for the centered vdP disk can also be determined from the FEM as indicated in Figures 5(a) and (b) (Moussa *et al*., 2001). Notice from Figure 5(a) that for zero field, current flows into the shunt along paths that are normal to the metal–semiconductor interface, whereas at high field current is mostly ejected from the shunt along paths that are approximately tangent to the interface.

2.4 Externally shunted rectangular EMR macroscopic structures based on conformal mapping

The centered vdP structure shown in the inset of Figure 2 is not compatible with the scaling of EMR devices to the nanoscale regime for applications such as read-head sensors because of the difficulty of fabricating and filling nanoscopic holes. However, one can use the concept of bilinear conformal mapping (Churchill, 1960) to generate structures that will exhibit EMR and at the same time will be compatible with nanoscale fabrication.

It is known (Popovic, 1991; Solin, 2004; Zhou, Hines and Solin, 2001) that any homogeneous device with a circular boundary of unit radius in the two-dimensional complex t plane with orthogonal axes r and is where $t = r + is$ can be

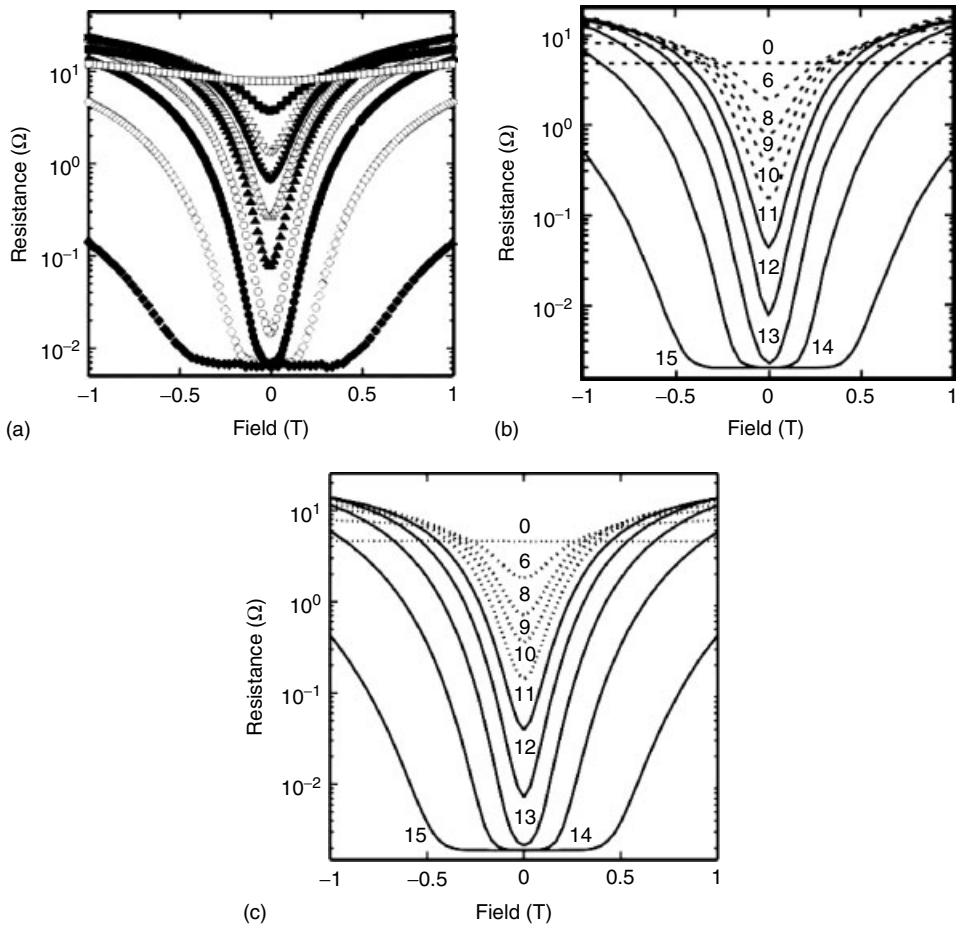

Figure 4. (a) The measured room-temperature field-dependent resistance up to 1 T of a composite van der Pauw disk of Te:InSb and Au for a number of values of $\alpha = r_a/r_b$. This is the data that was used to compute the EMR shown in Figure 2. The data traces in the region of zero field correspond (top to bottom) to increasing α in the following steps: $16\alpha = 0, 6, 8, 9, 10, 11, 12, 13, 14, 15$. (b) Field-dependent resistance calculated analytically using Laplace's equation with no adjustable parameters. (c) Field-dependent resistance calculated using the finite element method with no adjustable parameters. mapped into the complex upper half Cartesian z plane with orthogonal axes x and iy where $z = x + iy$ (see Figure 6a) by using the bilinear transformation (Popovic, 1991).

$$z(t) = -i\,\frac{t\ +\ i}{t\ -\ i} \tag{7}$$

The preceding mapping equation transforms the four symmetrically spaced electrical contacts on the perimeter of the disk in the t plane (shown in Figure 6a in the configuration for a MR measurement) to the corresponding contacts on the line $y = 0$ in the z plane. Although the mapped contacts are symmetric about the line $x = 0$ they are not of equal size as they are when viewed in the t plane. If one embeds an off-centered hole of radius r_1 into the homogeneous disk of Figure 6(a) as shown in Figure 6(b), that hole maps to a line that truncates the upper half plane at height $y_1 = 1/(r_1 + 1)$. In other words, the vacuum inside the hole of radius r_1 in the disk in the t plane maps to the vacuum above the line y_1 in the z plane. Consider now the circle of radius r_2 which creates an evacuated notch in the disk in the t plane as shown in Figure 6(c). That circle maps to a line which truncates the z plane at the position $x = x_2 = 1/r_2$ as is also shown in Figure 6(c). A symmetrically displaced circle of equal radius on the left of the vertical bisector of the disk in the t plane truncates the z plane with a line at position $-x_2 = -(1/r_2)$ as shown in Figure 6(d). By a selection of circular cuts in the t plane, the truncated disk can be exactly mapped to a rectangular structure of appropriate dimension in the z plane.

Of the structures depicted in Figures 6(a–d), that shown in Figure 6(b) is the simplest one which contains a fully enclosed inhomogeneity, for example, a circular hole displaced from the center of the disk. Zhou, Hines and Solin (2001) showed that if one embeds this hole with a highly

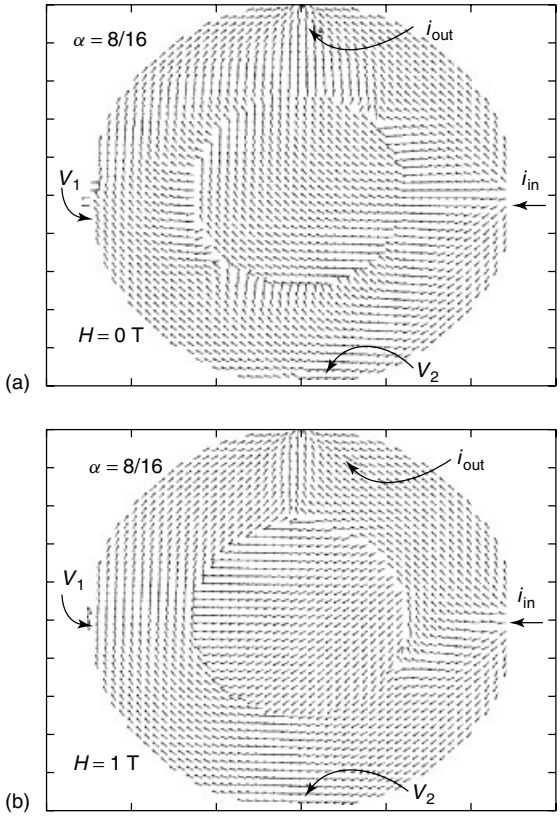

Figure 5. The current flow in the van der Pauw geometry for a circular InSb wafer with a concentric metallic inhomogeneity and $\alpha' = 8/16$, (a) at $H = 0$ and (b) at $H = 1\,\mathrm{T}$. conducting metal, then the resultant structure which they called an off-center vdP disk is similar to the centered vdP disk which yielded the large EMR values cited in the preceding text. However, the corresponding rectangular mapped structure in the z plane would be of infinite extent in the $+x$ and $-x$ directions and would contain an external shunt of infinite height in the $+y$ direction. To avoid these complications, Solin *et al*. defined a structure which contains not only the r_2 cuts of Figure 6(d) but also an additional circle of radius r_3 in the t plane as shown in Figure 6(e). The latter maps to the line $y = y_3$ in the z plane. The modified off-centered vdP disk now contains a metallic inhomogeneity embedded into the space between the circles of radii r_1, r_2, and r_3 while the space between the circle of radius r_1 and the disk perimeter contains a narrow-gap semiconductor. Thus, the t-plane disk with an *internal* embedded shunt maps to a rectangle in the z plane with a corresponding *external* metallic shunt, which was called a *van der Pauw plate* (Zhou, Hines and Solin, 2001). Moreover, for the exact mapping depicted in Figure 6(e), the galvanomagnetic behavior of the two structures will be identical (Popovic, 1991).

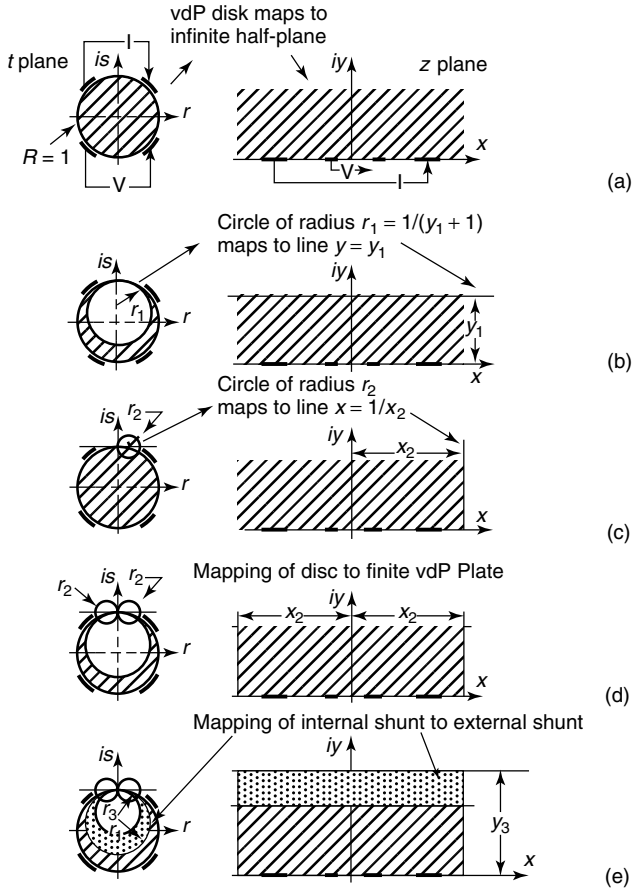

Figure 6. Schematic diagram of bilinear mapping of (a) a van der Pauw disk in the t plane mapped to the upper half space of the z plane. Also shown is the contact configuration for measuring magnetoresistance. (b) an off-center hole in the t plane mapped to a line in the z plane, (c) a circular perimeter cut in the t plane mapped to a line in the z plane, (d) repeat of (c) with a symmetric perimeter cut, (e) an internal shunt in the t plane mapped to an external shunt in the z plane. (Reprinted with permission T. Zhou *et al*., copyright 2001, American Institute of Physics.)

Although the mapping technique described in the preceding text, has been known, (Popovic, 1991) the adaptation of this technique to the design of rectangular structures with external shunts (Zhou, Hines and Solin, 2001) had not been previously considered. Furthermore, for mapped plates with $x_2 > 4$, the cuts represented by the circles of radius r_2 in the left panel of Figure 6(e) are small/negligible. Therefore, the externally shunted plate structure shown on the right panel of Figure 6(e) is, to a good approximation, electrically equivalent to the vdP disk shown in the left panel of Figure 6(e) without the r_2 cuts. Moreover, an expression for the filling factor of the rectangular EMR structure, though more complex than that of the concentric circular structure has been derived as a function of the geometric properties of the structure (Zhou, Hines and Solin, 2001).

In order to confirm that the mapping procedure described in the preceding text is viable it was tested using symmetric and asymmetric four-probe macroscopic vdP plate EMR structures of the type shown in the insets to Figures 7(a) and (b) (Solin, 2005). The results of these tests are shown in the main panels of Figure 7. The material constituents of the vdP plate structures depicted in the insets of Figure 7 were the same as those used for the internally shunted circular hybrid structures depicted in the inset Figure 2. Two features are noteworthy in the data of Figure 7(a) the room-temperature EMR is very large reaching values in excess of 100% at a field of 0.05 T. In Figure 7(b) the EMR is asymmetric with respect to the applied field when the leads are placed asymmetrically on the rectangular narrow-gap semiconductor plate. The latter feature constitutes a condition of self-biasing which is important for a number of applications in which the sign of the applied magnetic field must be determined.

The magnetotransport properties of the externally shunted vdP plate clearly depend strongly on the placement of the current and voltage leads, for example, on lead geometry.

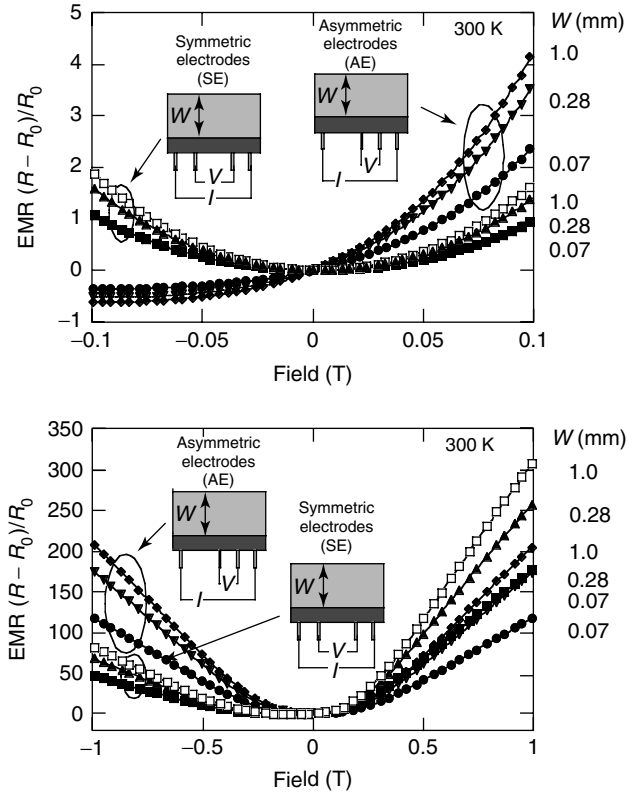

Figure 7. The low field (a) and high field (b) room-temperature EMR of van der Pauw plates with symmetric and asymmetric electrode configurations as a function of the width, W, of the external shunt. The dark (light) rectangle represents Te:InSb (Au). (Adapted from Figure 2 of Solin, 2004.)

These properties also depend strongly on the shape and relative dimensions of the semiconductor and metal components of the hybrid structure itself as can be seen from the dependence of the EMR in Figure 7 on the width, W, of the shunt for a semiconductor region of fixed width. Note that in the range of filling factors addressed in Figure 7 which is below the optimum filling factor of 13/16, as depicted in Figure 3, the EMR systematically increases with increasing filling factor. In addition, an added feature of the data of Figure 7 is the enhancement of the EMR in the structure with asymmetric leads relative to the structure with symmetric lead placement.

Moussa, Ram-Mohan, Rowe and Solin (2003) have used the FEM to calculate the EMR of four-probe vdP plates as a function of the position of a magnetic spot along the long axis of the semiconductor. They showed that the EMR response was strongly dependent on the wiring configuration of the four leads of the vdP plate and on the spot position along the long axis of the plate. For instance, as can be seen from Figure 8, the IVVI configuration gives an asymmetric response for the position dependent MR while the VIVI configuration yields a larger but inverted quasisymmetric response. Holz, Kronenwerth and Grundler (2005a) also employed the FEM to extend the theoretical studies of Moussa, Ram-Mohan, Rowe and Solin (2003). They showed that for an inhomogeneous field of a spot, the field-dependent resistance exhibits a symmetry reversal (*vis-à-vis* symmetric and antisymmetric) relative to that of a homogeneous field and that the active device area depended not only on the voltage probe positions but also on the locations of the current probes.

Holz, Kronenwerth and Grundler (2005a) also developed a clever method for assessing and illustrating the effect of an inhomogeneous field. They defined the MR of a dot as $MR_{\mathrm{dot}} = [R\,(B_{\mathrm{dot}} = +50\,\mathrm{mT}) - R\,(B_{\mathrm{dot}} = -50\,\mathrm{mT})]\,/\,R\,(0)$ and displayed MR_{dot} for different lateral positions as a grey-scale pattern as shown in Figure 9. Holtz *et al.* have also studied the response of vdP plate EMR structures with the FEM to determine the optimal EMR as a function of the geometry, for example, length (L) to width (W) ratio and material parameters (Holz, Kronenwerth and Grundler, 2003). They confirmed the correlation of the asymmetric (symmetric) response with and IVVI (IVIV) lead configuration and found that EMR is optimal for devices with $L/W = 0.025$. Most importantly, they showed (i) that EMR vdP plates are inversely scalable, for example, their performance improves with *decreasing* size, (ii) that the EMR can be further enhanced/optimized by selective placement of the voltage and current leads (Holz, Kronenwerth and Grundler, 2005b), and (iii) that for the IVIV configuration, the Hall effect and EMR cooperate to enhance sensitivity (Holz, Kronenwerth and Grundler, 2005b).

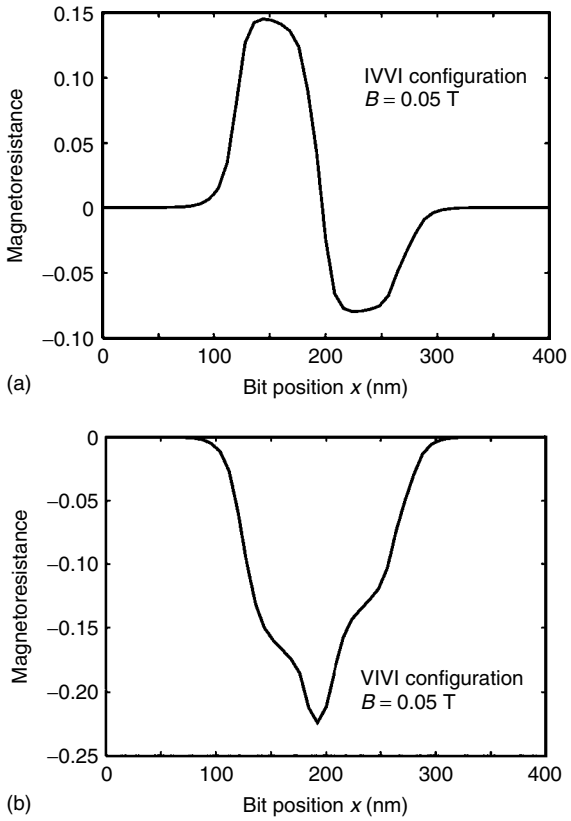

Figure 8. (a) The calculated magnetoresistance of a symmetric van der Pauw plate structure (see insets of Figure 7) as a function of the position of an $80 \times 50\,\mathrm{nm}^2$ magnetic bit with a magnetic field of 0.05 T. The external leads are 20 nm thick, with the leads centered at ± 150 nm and ± 30 nm. The leads are wired in the IVVI configuration. (b) The same as (a) but with the leads wired in the IVIV configuration. (Reprinted with permission Moussa *et al.*, copyright 2003, American Institute of Physics.)

2.5 Nanoscopic EMR devices

Several applications of state-of-the-art magnetic sensors including imaging, medical devices, and read heads for ultrahigh-density magnetic recording require structures with three-dimensional spatial resolution at the nanoscale. In the case of EMR sensors, one requires an ultrathin (<100 nm) film, which can be patterned into device structures with lateral dimensions of order 50 nm. Unfortunately, the mobility of InSb on GaAs (100) drops drastically with thickness for thicknesses below 1000 nm as a result of carrier scattering from dislocations induced by the 14% lattice mismatch (Zhang *et al.*, 2004). To overcome this problem, Solin and coworkers designed a nanoscopic four-lead vdP plate EMR device (Solin *et al.*, 2002a,b) based on an InSb/AlInSb quantum-well heterostructure (Chung *et al.*, 1999) which exhibits relatively high mobility for carriers in the very thin well.

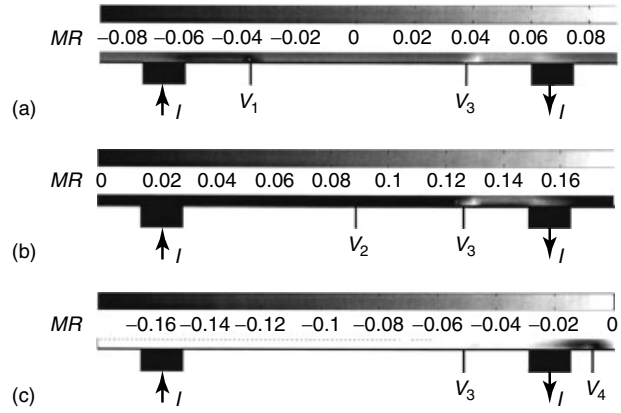

Figure 9. Magnetoresistance, $MR_{\mathrm{dot}} = [R(B_{\mathrm{dot}} = +50\,\mathrm{mT}) - R(B_{\mathrm{dot}} = -50\,\mathrm{mT})]/R(0)$, of the hybrid structure for different voltage probe configurations: (a) $V_1 - V_3$, (b) $V_2 - V_3$, and (c) $V_3 - V_4$ as a function of the dot's position in the semiconductor. For clarity, the metal is not shown here. In each figure, black represents the lowest and white the highest possible value. Note that the dynamic range in each sub figure is the same. (Reprinted with permission M. Holz *et al.*, copyright 2005, American Institute of Physics.)

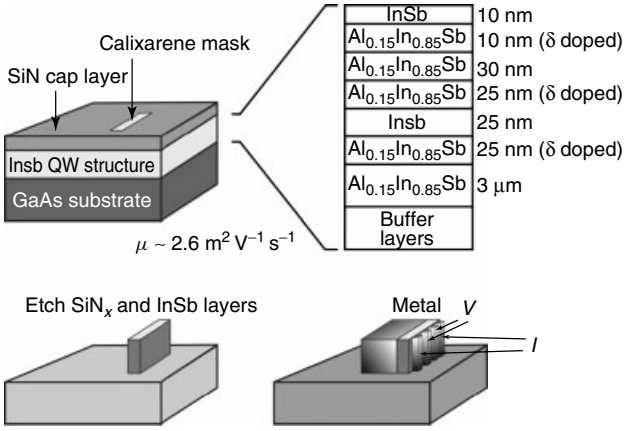

Figure 10. A schematic representation of the process used to fabricate nanoscopic EMR structures.

In Figure 10 is shown schematically the nano-EMR quantum well layer stacking arrangement together with the (simplified) fabrication steps that are required. To achieve lateral feature sizes below 100 nm, a multistep state-of-the-art electron beam (e-beam) lithography process was utilized (Solin *et al.*, 2002a). First, a 30-nm-thick insulating film of Si_3N_4 was deposited on the thin-film-quantum-well wafer as a cap layer and macroscopic Au strips for wire bonding were deposited. Then a 30-nm-thick film of calixarene, a new high-resolution negative resist (Yasin, Hasko and Carecenac, 2001) was spin-coated on. The desired lithographic pattern was delineated in the calixarene by e-beam lithography. This calixarene pattern and the macroscopic Au strips

serve as a mask for reactive ion etching (RIE) (Roosmalen, Baggermann and Brader, 1995) of the Si_3N_4 layer using standard methods (Sugawara, 1998). This etching process produces a raised mesa of the thin film on its supporting substrate. For InSb films, the appropriate etchant is a CH_4+H_2 mixture. The residual Si_3N_4 and Au strips serve as an RIE mask. Au leads and Au bridging contacts were then deposited using a Ge stencil mask and shadow evaporation technique. To minimize leakage current through the floor of the mesa, as evidenced by finite EMR observed in shuntless devices, an insulating Al_2O_3 barrier was first prepared by depositing and subsequently oxidizing a layer of Al close to the mesa sidewall. In addition, extremely high alignment accuracy of about ± 10 nm was required to effect sidewall contacting of the Au strips to mesa at the location of the quantum well.

The above-described e-beam lithographic methods, were used to fabricate the nano-EMR structure shown in Figure 11. The active volume of this structure has dimensions of order the width of the mesa at the height of the quantum well (30 nm) $\times$ the spacing of the voltage probes (40 nm) $\times$ the thickness of the quantum well (25 nm). The field dependence of the room-temperature MR of that device is shown in the main panel and upper-right inset of Figure 12. As can be seen, the EMR reaches values as high as 5% at zero bias and a signal field of 0.05 T. This was claimed to be the highest room-temperature MR level obtained to date for a patterned magnetic sensor with this spatial resolution (Solin*et al*., 2002b). Moreover, with a modest bias field of 0.2 T corresponding to the zero-field offset (Solin *et al*., 1996) in Figure 12, the measured EMR is 35% at a signal field of 0.05 T. (The offset is associated with the asymmetric placement of the voltage leads.) Also, note that the device can be biased into a field region where the EMR response is linear with field, a feature that can simplify signal amplification. Equally significant is the fact that the current sensitivity, at

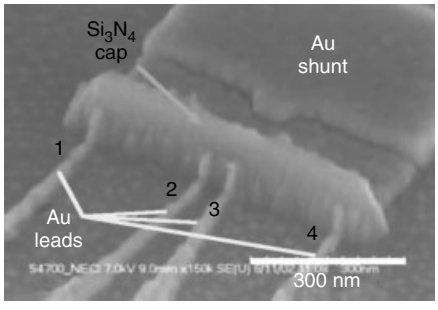

Figure 11. An electron micrograph of a hybrid nanoscopic van der Pauw EMR plate structure fabricated from an InSb/$In_{1-x}Al_xSb$ quantum-well heterostructure. The current leads, voltage leads, and external shunt are labeled as indicated. The four contacts shown in the micrograph extend along the mesa floor and up the side of the mesa to the upper 25 nm $Al_{0.15}In_{0.85}Sb$ barrier. (Adapted from Figure 3 of Solin, 2005.)

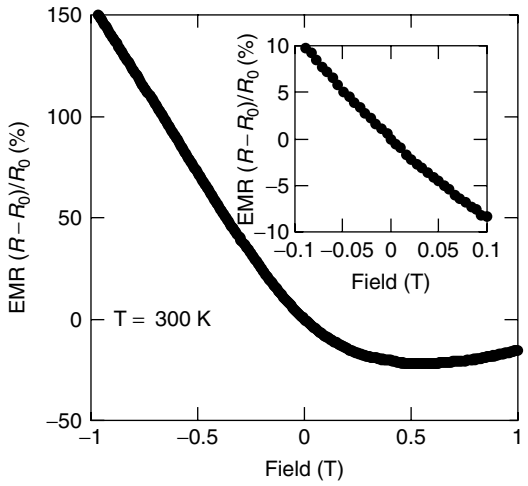

Figure 12. The field dependence of the magnetoresistance of the mesoscopic van der Pauw plate structure shown in Figure 11. The bias current density is 5×10^3 A cm^{-2}.

a magnetic field bias of 0.2 T has a large measured value of 585 Ω T^{-1} at room temperature. It is this figure that enters directly into the calculation of the signal-to-noise ratio (SNR) as will be discussed in the subsequent text.

The room-temperature mean free path of the carriers in an InSb quantum well is $\ell = \hbar\sqrt{2\pi\tilde{n}}(\mu/e) = 200$ nm (Jablonski *et al*., 1984). Thus one would expect the transport in a nanostructure to be ballistic in which case it can be shown that the expected EMR would be at least a factor of 5 lower than what is observed in Figure 12. However, Solin *et al*. have suggested that the transport is in fact still diffusive as a result of the randomization of the carrier velocities due to scattering off of the rough mesa sidewalls (Solin *et al*., 2002a,c) (see Figure 11). The scattering process is enhanced because the roughness wavelength is of the order of the Fermi wavelength of the carriers $\lambda_F = \sqrt{2\pi/\tilde{n}} =$ 48 nm (Jablonski *et al*., 1984). Given the assumption of diffusive transport, the EMR of the nanoscopic device though noteworthy, is still about a factor of 20 lower than that obtained with a macroscopic plate of the same geometry fabricated from thin film Te-doped InSb with a room-temperature mobility of 4.5×10^4 cm^2 Vs^{-1} (Zhou, Hines and Solin, 2001). Part of this difference is due to the mobility difference thus yielding a reduction in EMR of a factor of $(4.5 \times 10^4/2.3 \times 10^4)^2 = 3.8$. The additional order of magnitude reduction derives from current leakage through the mesa floor (quantum well lower barrier) which carries a much higher proportion of the current than does the quantum well itself.

The performance of a magnetic sensor is, of course, measured by the SNR at the operating conditions under which it will be employed. For nano-EMR devices of the

type shown in Figure 11, only two noise sources are relevant, $1/f$ noise and thermal or Johnson noise. In this case, if the effective resistance is quadratic with field, for example, $R^{\text{eff}} = R_0^{\text{eff}}\left[1 + G\mu^2(H - H_0)^2\right]$ where H_0 is the zero-field offset, the voltage SNR can be written in the following form (Weissman, 1988; Solin 2007):

$$SNR(f) = \frac{I_{\text{in}}\left|\left(\frac{\mathrm{d}R^{\text{eff}}}{\mathrm{d}H}\right)_{H_{\text{bias}}}\right|\Delta H}{\left[\left(\frac{V}{L}\right)^2\gamma\mu e R_{\text{out}}\frac{\Delta f}{f} + 4kTR_{\text{out}}\Delta f\right]^{\frac{1}{2}}} = \frac{\left|El[(2G_S\mu^2 H_{\text{Bias}} \pm G_{\text{AS}}\mu)\Delta H]\right|}{\left[\frac{E^2\gamma l}{nwt}\frac{\Delta f}{f} + \frac{4kTl\Delta f}{nwte\mu}\right]^{\frac{1}{2}}} \quad (8)$$

where I_{in} is the input current, V is input voltage, $L(l)$ is the spacing of the current (voltage) leads, γ is the dimensionless Hooge parameter (van der Ziel, 1988), e is the electron charge, f is the operating frequency, Δf is the detection bandwidth, k is Boltzmann's constant, T is temperature in Kelvin, R_{out} is the two terminal resistance between the voltage probes including the contact resistance at the interface between the voltage probes and the device, $E = V/L$ is the bias electric field, l is the voltage probe spacing, n is the carrier (electron) density, wt is the cross-sectional area for bias current flow and the other variables in equation (8) have been previously defined. The first term in each of the denominator brackets is the 1/f noise while the second term is the thermal noise. By equating these two terms we can deduce the crossover frequency $f_c = E^2(\gamma e\mu/4kT)$. For $f \gg f_c$ thermal noise dominates and the SNR is frequency independent, while for $f \ll f_c$ 1/f noise dominates and the SNR is independent of the bias field.

It is useful to estimate the crossover frequency for a nanoscopic EMR sensor of the type shown in Figure 11. The relevant parameters are $\gamma \sim 10^{-8}$, $\mu \sim 2.3 \times 10^4\,\text{cm}^2\,\text{V}^{-1}\,\text{s}^{-1}$, $E \sim 4 \times 10^2\,\text{V cm}^{-1}$ in which case $f_c \sim 400\,\text{Hz}$ at 300 K. Clearly, it is desirable to operate the EMR nanosensor at sufficiently high frequency to be in the thermal noise limited region. Note that l, w, and t are set by the required three-dimensional resolution, and ΔH is set by the available signal so these parameters are deemed uncontrollable.

In the thermal noise regime, the SNR increases as $n\mu^{5/2}$. Therefore, it is advantageous to maximize this product. Since for $n(T) > n_c(T)$ mobility decreases with increasing n (Seeger, 1985), where $n_c(T)$ is a critical concentration, EMR nano sensors operate optimally at or near $n_c(T) = n_c(300\,\text{K})5 \times 10^{17}\,\text{cm}^{-3}$ for InSb (Madelung, 1991). For an EMR nanosensor with this carrier concentration and dimensions shown in Figure 11, the calculated noise equivalent field (NEF) (Deeter, Day, Beahn and Manheimer, 1993) that is obtained from equation (8) by setting $SNR(f) = 1$ and solving for the resultant value of $\Delta H/\sqrt{\Delta f}$ is NEF = $4.1\mu\,\text{T Hz}^{-1/2}$ for a bias current of 2.2×10^{-6} A, a current sensitivity of $585\,\Omega\,\text{T}^{-1}$. For comparison, nano-Hall sensors with active area $50 \times 50\,\text{nm}^2$ made from bismuth have a reported NEF of $100\,\mu\text{T(Hz)}^{-1/2}$ (Sandu, Kurosawa, Dede and Oral 2004), while micron-size Hall devices based on GaAs/AlGaAs quantum wells have been demonstrated in scanning probe systems that show NEF of $4\,\mu\text{T(Hz)}^{-1/2}$, but only at low temperature (<77 K) (Bending, 1999). Also TMR and GMR sensors with flux concentrators show NEF as low as $0.1\,\text{nT(Hz)}^{-1/2}$ at room temperature but this corresponds to spatial resolutions of the order of microns (Stutzke, Russek, Papas and Tondra, 2006).

3 BALLISTIC MAGNETORESISTANCE

3.1 Transport through a point contact

In the BMR phenomenon (Garcia, Munoz and Zhao, 1999), we again see a manifestation of the *geometric* enhancement of the MR. The resistance in a point contact between two ferromagnetic wires, as shown in Figure 13, is governed by quantum-mechanical effects associated with the ballistic transport of electrons from one wire to the other through a channel of nanometer dimensions. The wires can be considered to be reservoirs of electrons with a difference in their chemical potentials due to a bias, so that a current can flow from one side of the device to the other. The actual resistance depends on the size of the diameter at the contact, which is typically over several atomic 'channels' all the way down to a single atomic point contact. Each channel acts as a waveguide for the electron, and the transmission coefficient for the waveguide defines the strength of the contribution for each mode in the waveguide; the transmission coefficient depends strongly on the geometry of the waveguide.

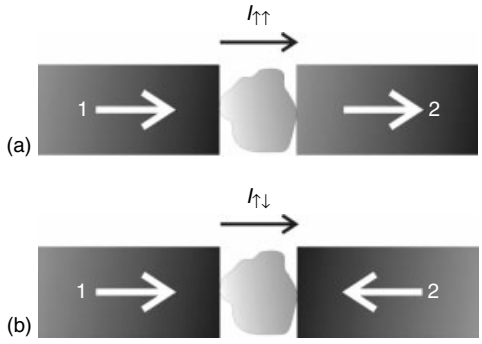

Figure 13. A schematic of a cluster of Ni or Co atoms deposited between two ferromagnetic wires for which the magnetization in the two wires is (a) parallel, or (b) antiparallel.

For normal metallic point contacts with N noninteracting independent channels and with unit transmission, the quantization of the conductance G is described by Landauer (1957, 1970, 1988), and Buttiker, Imry, Landauer and Pinhas (1985) to be

$$G = 2e^2 \frac{N}{h} = \frac{N}{(25.8\,\mathrm{k}\Omega)} \tag{9}$$

Because this result is central to our understanding of BMR we provide, in Appendix A, a detailed derivation of it. The factor of 2 in the conductance formula accounts for the fact that in such metallic contacts electrons of both spin polarization are transported across the contact. For ferromagnetic leads with a point contact between them, the transport of electrons across from one wire to the other is, in general, a spin-dependent process. We are then concerned with *spin*-ballistic transport through the junction. In the case of BMR, the two reservoirs are ferromagnetic and have particular spin polarizations which are either parallel or antiparallel to each other. The unit of conductance is defined by $G_{0\uparrow\uparrow} = e^2/h$, without the factor of 2 of the usual theory that accounts for both electron spins (Ono, Ooka and Miyajima, 1999). In Figure 13, which show a schematic of a BMR contact structure, the magnetization of the two ferromagnetic wires is parallel in configuration (a), and antiparallel in configuration (b). The nanoscale point contact between the wires is represented by a cluster of atoms between the tips of the wires. The switching of the magnetization in the wire labeled 2 on the right can be controlled by an external magnetic field applied to this wire. The conductance of the nanochannel changes with the application of the external magnetic field leading to the BMR which is defined as

$$[\mathrm{BMR}] = \frac{\Delta G}{G} = \frac{G_{\uparrow\uparrow} - G_{\uparrow\downarrow}}{G_{\uparrow\downarrow}} \tag{10a}$$

or equivalently as

$$[\mathrm{BMR}] = \frac{\Delta R}{R} = \frac{R_{\uparrow\downarrow} - R_{\uparrow\uparrow}}{R_{\uparrow\uparrow}} \tag{10b}$$

In 1999, the initial observations (Garcia, Munoz and Zhao, 1999, 2000; Landauer, 1957; Ono, Ooka and Miyajima, 1999; Zhao, Munoz, Tatara and Garcia, 2001) at room temperature were of a BMR of 280% with 3d transition metals (Fe, Co, Ni) using atomic size contacts. These were followed by a BMR of 700% in electrodeposited Ni–Ni nanocontacts of 30 nm (Garcia *et al*., 2001). More recently, Chopra and Hua (2002) have observed a room-temperature BMR of 3150% using electrodeposition of the nanocontact.

The reader should beaware that the experimental evidence for BMR is still in a state of flux because of the difficulties and pitfall with the experiments (Eglekoff *et al*., 2005).

3.2 Theoretical aspects of domain wall scattering

Theoretical considerations suggest that the BMR effect is generated by spin scattering at domain walls (DWs). The presence of a DW in the nanochannel for the antiparallel configuration, then leads to enhanced scattering that depends on the geometry of the contact and the structural (and spatial) details of the DW. The width of the wall depends on the area of contact and the size of the junction. The enhanced scattering in the antiparallel configuration corresponds to the relation

$$G_{\uparrow\uparrow} > G_{\uparrow\downarrow} \tag{11}$$

The early work of Cabrera and Falicov (1974) on the scattering mechanism for an electron scattering off a DW in a bulk material provides a framework to consider the effect of scattering. Their work was based on a classical Boltzmann equation model, and was in the limit that the thickness of the DW, d_w, is much less than the mean free path. It showed that the resistivity is large only when the spin splitting is comparable to the Fermi energy and $k_\mathrm{F} d_\mathrm{w} \leq 1$, where k_F is the Fermi wave vector. A limitation of their work is that it considers only one-dimensional motion for the electrons. Tatara and Fukuyama (1997) treated the three-dimensional motion of the electrons and considered the effect of a DW on the resistivity in a mesoscopic wire of width L_T with the DW thickness $d_\mathrm{w} \geq L_T \gg k_\mathrm{F}^{-1}$. However, again, in this case, the electron spin can accommodate itself adiabatically from one side of the DW to the other. Thus, the reflection of the electron at the wall is negligible, resulting in a very small MR.

In both cases, the overall MR effect is small as compared with nanoscale point contacts. In thick DWs, the MR is reduced because the spin can rotate and align with the local magnetization adiabatically as the electron travels through the wall. Conversely, for very thin DWs ($\sim$1 nm) the spin is almost completely conserved as the electron crosses the wall. However, this is no longer true if the contact size is of nanometer scale and we have quantized conductance. The thickness of the DW may then be very thin, of the order of the contact size, and yet the BMR should be very large even at room temperature (RT) because, in this case, the adiabatic accommodation of the spin polarization as the electron traverses the DW does not hold. This has indeed been indicated in the calculation in the limit of a vanishing DW width by van Hoof *et al*. (1999). Through the use of realistic band structure calculations they were able to show that the DW MR is enhanced by orders of

magnitude over the results from earlier theories. Tatara, Zhao, Munoz and Garcia (1999) calculated the resistivity based on the exchange interaction between the local spin S of the ferromagnetic ions and the electron spin. Using a Hamiltonian of the form

$$H = \sum_{k\sigma} \varepsilon_k c^+_{k\sigma} c_{k\sigma} - J \int \mathrm{d}x\, S(x)(c^+ \sigma\, c) \tag{12}$$

with $\varepsilon_k = \frac{\hbar^2 k^2}{2m} - \varepsilon_\mathrm{F}$ and a local spin S having the spatial dependence of a DW ($S_z = S_0$ tanh (x/d_w)), they showed that the resistance due to the DW is given by

$$R_\mathrm{w} = \frac{h}{e^2}\frac{1}{N}\frac{\pi^2}{4}\frac{\zeta^2}{1-\zeta^2}F(\zeta, d_\mathrm{w}) \tag{13}$$

with N being the number of channels in the cross-sectional area of the contact, while $\zeta = (k_{\mathrm{F}\uparrow} - k_{\mathrm{F}\downarrow})/(k_{\mathrm{F}\uparrow} + k_{\mathrm{F}\downarrow})$, and $k_\mathrm{F} = (k_{\mathrm{F}\uparrow} + k_{\mathrm{F}\downarrow})/2$. The parameter ζ is the spin polarization at the Fermi level ε_F and it also corresponds to the ratio of the density of states at ε_F, so that $\zeta = (D_\uparrow - D_\downarrow)/(D_\uparrow + D_\downarrow)$. The function $F(\zeta, d_\mathrm{w})$ is

$$F(\zeta, d_\mathrm{w}) = \frac{1}{2}\left[\frac{1}{\cosh^2 \pi\, k_\mathrm{F} d_\mathrm{w}} + \frac{1}{\cosh^2 \pi\, k_\mathrm{F}\zeta\, d_\mathrm{w}}\right] \tag{14}$$

and is shown in Figure 14. In the absence of a DW the conductance is given in terms of the number, N, of channels through the contact as $G_{\uparrow\uparrow} = Ne^2/h$. The DW resistance R_w and $G^{-1}_{\uparrow\uparrow}$ arise from different mechanisms and the total resistance is $R = G^{-1}_{\uparrow\uparrow} + R_\mathrm{w}$. We can then identify the BMR as arising from the presence or absence of R_w in $G = R^{-1}$

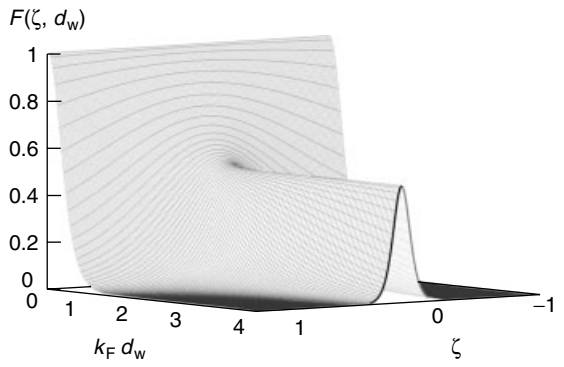

Figure 14. The function $F(\zeta, d_\mathrm{w})$ is plotted as a function of the spin polarization parameter ζ and the effective domain wall thickness expressed as $k_\mathrm{F} d_\mathrm{w}$. As $d_\mathrm{w} \to 0$, we have $F(\zeta, d_\mathrm{w}) \to 1$. For large values of $k_\mathrm{F} d_\mathrm{w}$, the function $F(\zeta, d_\mathrm{w})$ shows a peak at $\zeta \to 0$ with a maximum of 0.5.

and we have

$$\frac{\Delta G}{G} = \frac{G_{\uparrow\uparrow} - G_{\uparrow\downarrow}}{G_{\uparrow\downarrow}} = \frac{\pi^2}{4}\frac{\zeta^2}{1-\zeta^2}F(\zeta, d_\mathrm{w}) \tag{15}$$

For further details of the derivation, the reader is referred to the article by Tatara, Zhao, Munoz and Garcia (1999). The function $F(\zeta, d_\mathrm{w}) \to 1$ as the DW d_w goes to zero (see Figure 14). This prediction of the theory is in agreement with the model of Julliere (1975), who investigated the tunneling across an interface between two ferromagnetic films, when the spin is conserved across the interface. In other words, the BMR is given by the degree of polarization only. Also, $F(\zeta, d_\mathrm{w}) \to 0$ as the DW thickness increases, so that $k_\mathrm{F} d_\mathrm{w} \geq 1$, and the electron spin accommodates the spin variation in the DW. When the material has only one spin-polarized band we have $\zeta \to 1$, and the magnetoconductance (MC) goes to infinity, according to equation (15). This corresponds to total reflection at the interface.

In explicitly obtaining $F(\zeta, d_\mathrm{w})$, for the ferromagnetic materials, it is necessary to know the density of states at the Fermi level from band structure calculations (Moruzzi, Janak and Williams, 1978), since both s and d bands contribute to the density of states at the Fermi level. The ratio of the total density of states for the two bands to that of the s band at the Fermi level, $\beta = D_{\mathrm{d+s}}/D_\mathrm{s}$, is large since it is the d-band density of states that dominates in these materials. Assuming that the band structure in the thin ferromagnetic wires on either side of the nanocontact is close to that of the bulk material we can‘ theoretically estimate for Ni that $\beta \approx D_\uparrow/D_\downarrow = 13$, and that $\zeta = 0.87$. Garcia *et al.* (2001) estimated that this provides a maximum MR of 400% which agrees remarkably well with experiments (Garcia, Munoz and Zhao, 1999). For Co, the values of the parameters are $\beta \approx 11$ and $\zeta = 0.83$. The number of channels N participating in the ballistic transport can be estimated using Sharvin's formula (Sharvin, 1965a,b) in which the β parameter, representing the large density of states at the Fermi level, and the geometric parameter a, the radius of the contact, play a role. We have

$$N = \beta\frac{(k_\mathrm{F} a)^2}{4} \tag{16}$$

Now, d_w, is also related to the number of channels through the fact that in nanocontacts the restricted channels alter the geometry of the DW so that with the assumption $d_\mathrm{w} \approx a$, equation (16) leads to the relation

$$k_\mathrm{F} d_\mathrm{w} = k_\mathrm{F} a = \left(\frac{4N}{\beta}\right)^{1/2} \tag{17}$$

Analytical calculations showing that $d_\mathrm{w} \approx a$ have been performed by Bruno (1999).

Thus, the MC, equation (15) is large, even for small N, when $\zeta \approx 1$ and decreases rapidly as the number of channels increases beyond $N \geq \beta/4$.

The ballistic transport through a connecting narrow nanochannel between two ferromagnetic regions has been modeled by Tagirov, Vodopyanov and Efetov (2001, 2002) and Tagirov, Vodopyanov and Garipov (2003) by considering actual circular and rectangular geometries for the contact. The effect of a DW and its width, in comparison with the spin mean free path, on the BMR can then be studied, and the models reproduce the experimental results of Garcia, Munoz and Zhao (1999) fairly well. The location of the DW in the ballistic channel, between the two ferromagnetic regions, is included in their discussion. A tight-binding model for the theory of tunneling magnetoresistance has been developed by Mathon (1997), who shows that the tunneling MR approaches rapidly the same saturation value when either the interelectrode hopping decreases or the height of the insulating barrier increases. When the insulating barrier is high (i.e., the band gap is large), the tunneling MR depends only weakly on the thickness of the insulating layer. However, when the band gap is small compared to the conduction bandwidth, the tunneling MR decreases rapidly with increasing thickness of the insulator. Mathon's numerical results for a Co(001) junction, based on a fully realistic band structure of the Co electrodes, show a very similar behavior. As the tight-binding hopping matrix between the Co electrodes is gradually turned off, the tunneling MR ratio drops initially very rapidly from its value of 280% in the metallic regime to about 40% but then stabilizes in the range 40–65%. This is in a very good agreement with the observed value of 40%. It is thus noteworthy that he obtains very reasonable values for MR, using the tight-binding model, that agree with experiment. The tunneling MR in this model calculation is the BMR.

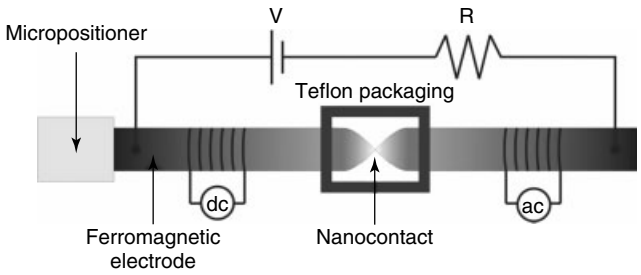

Figure 15. A schematic of the experimental setup employed by Garcia *et al*. is shown. (Reprinted with permission Chung *et al*., copyright 2003, American Institute of Physics.)

3.3 Experimental results on BMR

We now turn to the experimental results reported by Garcia, Munoz and Zhao (2000) and Garcia *et al*. (2001). A typical experimental schematic (Chung *et al*., 2003) is shown in Figure 15. The nanocontacts are formed by mechanically putting into contact the polished ends of two Ni wires of 2 mm diameter. The Teflon packaging mechanically holds and aligns the structure in place. By systematically moving the position of one of the wires, the contact area can be adjusted. The two ferromagnetic wires have wires wrapped around them to provide control in the direction of magnetization. At the tip of the nickel rods a field of up to 150 Oe is generated at 0.2 A. Alternating the current in one of the wire wrappings, leads to an alternating field on one of the ferromagnetic wire. This permits a clean measurement of the BMR. To determine the BMR, a 100 mV bias voltage was applied across the junction. Other materials could be deposited at the tip to investigate the BMR in nanochannels made with these materials. To summarize the experimental outcomes, the results (Garcia, 2003) of several measurements of the MC plotted against the conductance, or equivalently the number of channels N, is shown in Figure 16. Data from Co, Ni, and Fe nanochannels are presented in the same figure simultaneously. Reproducible results have been reported for the BMR (Chung *et al*., 2003). The measurements of BMR ranging from over 300% for narrow (atomic) channels of size ∼0.5 nm with $N = 1$, to 20% with N ∼ 20 channels with 2 nm^2 area of contact are shown. The full and dashed curves in Figure 16

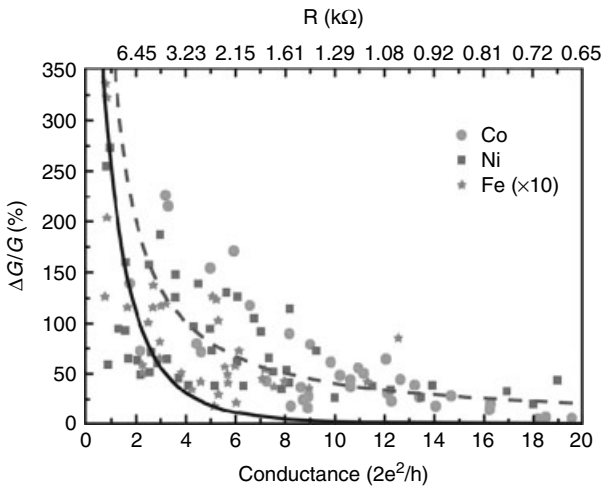

Figure 16. Magnetoconductance as a function of the contact conductance (bottom x axis) and the contact resistance (top x axis) for Ni, Co, and Fe contacts. Solid and dashed curves are the theory approximations in the limits of a small and large number of conducting channels, respectively. (Adapted from Figure 1 of Garcia, 2003.)

correspond to values of $\beta \approx 11$ and $\beta \approx 40$, respectively. It is seen that all the data lie between these two curves. While the lower value of the ratio of the density of states, β, is given by theoretical estimates of the band structure of the bulk material, this does not necessarily apply to the nanostructure.

3.4 Scaling and universality in BMR experiments

On putting together all the data on MC (or equivalently MR, as seen from equations (10a and b) for nanocontacts between Ni–Ni, Co–Co, Fe–Fe, CrO_2–CrO_2, and CrO_2–Ni heterojunctions, it was noticed by Chung *et al.* (2002) that the largest MR was observed at a conductance of $0.05\,G_0$ where $G_0 = 2e^2/h$. This is shown in Figure 17(a). This is different from the maximum for MR of ∼210% observed in Ni–Ni nanojunctions at a conductance of G_0. The behavior of CrO_2–Ni nanojunction is similar to that of CrO_2–CrO_2 in that the peak MC occurs at very low conductance although the maximum MR is lower, as seen in Figure 17(b). Chung *et al.* then combined the data for all nanocontacts by plotting the MC that is scaled by the maximum value of the MC in each of the heterojunctions. The quantity $(\Delta G/G_{\uparrow\downarrow})/(\Delta G/G_{\uparrow\downarrow})_{\max}$ was plotted against the conductance G_0. All the experimental data essentially fit *around* the solid curve and *within* the cross-hatched area between the solid and dashed curves of Figure 18. The solid and dashed curves are obtained from Tatara, Zhao, Munoz and Garcia (1999) for small N and for large N, the number of conducting channels, or equivalently when the DW

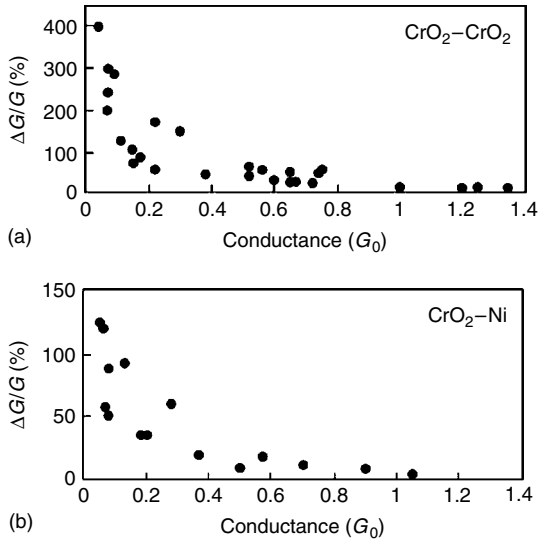

Figure 17. The experimental data for magnetoconductance versus contact conductance for (a) CrO_2-CrO_2, and (b) CrO_2-Ni nanocontacts. (Reprinted with permission Chung *et al.*, copyright 2003, American Institute of Physics.)

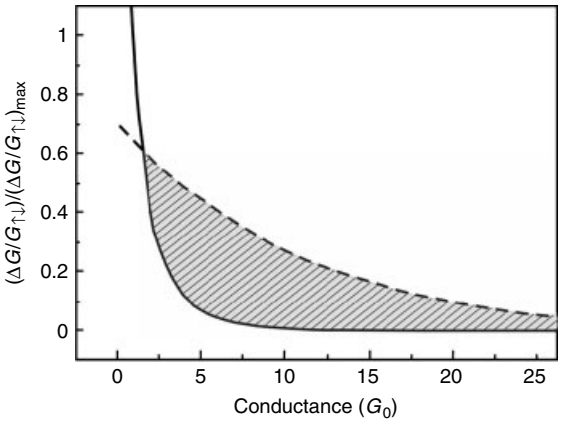

Figure 18. The universality of scaled BMR discovered by Garcia *et al.* is shown. The normalized magnetoconductance scaled by the ratio of the maximum BMR for the material. All experimental data essentially fit *around* the solid curve and *within* the cross-hatched area between the solid and dashed curves. The curves are obtained from Tatara *et al.* for small and large number of conducting channels. (Reprinted with permission Chung *et al.*, copyright 2003, American Institute of Physics and Chung *et al.*, copyright 2002, American Physical Society.)

magnetization profile varies smoothly or is constant in the DW, respectively. In the case of the CrO_2–Ni heterojunction, the scaling was performed using the conductance value of CrO_2. Figure 18 is a summary of the data for Ni, Co, Fe, the half-metallic CrO_2, Ni–CrO_2, and for the Verwey insulator Fe_3O_4 (Versluijs, Bari and Coey, 2001).

A universal picture for BMR for such a wide variety of materials occurs when the scaling of the data proposed by Chung *et al.* (2002) is performed. The normalized MC in nanocontacts has a universal behavior versus the scaled conductance, and is independent of the electron transport mechanism. The only consideration is spin conservation in the ballistic transport through the DW at the nanocontact. We follow the arguments of Chung *et al.* (2002) in presenting their analysis of the BMR. The behavior of the normalized MC is defined by the spin scattering function $F(\zeta, d_w)$ that incorporates the influence of the dependence on d_w and density of states at the Fermi level. When the Landauer conductance, $G = G_0 \sum_i T_i$, where T_i are the transmission coefficients, is reexpressed using Sharvin's version (Sharvin, 1965a,b), we have

$$G = G_0 \left(\frac{d_w}{\lambda_F}\right)^2 \gamma \tag{18}$$

where the number of channels $N = (d_w/\lambda_F)^2$, λ_F is the electron wavelength at the Fermi level, and γ is the transmission coefficient per channel. We can analyze the data after scaling using equation (18). Here the various factors take into account the different material resistivities since the DW scattering occurs in the nanochannel and the channel

transmission coefficient depends on the transport process and hence the resistivity. Therefore if $\gamma \ll 1$, then the conductance can be much smaller than G_0 even if the number of channels is larger than 1. The half-metallic oxide samples manifest this behavior whereas normal metals do not, and this explains the difference in scale on the graphs in Figures 16 and 17.

The theoretical work of Tagirov, Vodopyanov and Efetov (2001, 2002) and Tagirov, Vodopyanov and Garipov (2003) shows that large MR can occur in nanocontacts even in the diffusive regime. According to their quasiclassical theory of spin transport through magnetic nanocontact, large MR can be obtained if strong spin scattering at the DW is achieved for antiparallel alignment of magnetization in the magnetic nanocontact. Figure 19 provides a schematic representation of the DW within a nanocontact. To realize such large spin scattering, the electron spin orientation should be preserved during transit through nanocontacts. If DW width d_w is shorter than the mean distance between spin-flip scattering $d_{spn} = v_F T_{spin}$, where v_F is the Fermi velocity and T_{spin} is the spin-relaxation time, the spin can be preserved and large MR can be obtained even in the diffusive transport regime. Furthermore, they have predicted that the nanocontact of highly spin-polarized metals such as LSMO and CrO_2 would show very large MR of 1000% or higher. The mean free path ℓ of CrO_2 is about 1.4 nm or less at room temperature, as shown theoretically by Lewis, Allen and Sasaki (1997). The value is very small compared to that of normal metals, which is in the range of a few tens of nanometers. Also, Park *et al*. do obtain short spin diffusion lengths $\sim 3 \pm 1$ nmin another system, VIZ., NiCr (Park *et al*., 1999). Therefore, diffusive transport seems to be dominant at CrO_2 nanocontacts when $\ell < d_w$. On the other hand, the spin orientation can be preserved even after many scattering events. Therefore, when the DW width, assumed to be of the order of the square root of the nanocontact cross section, is smaller than the spin-relaxation length, the electron spin relaxation cannot be accommodated by the abrupt magnetization gradient and thus strong spin scattering, that is, high MR, can be achieved. The reader interested in further details of the scaling and universality in BMR and the nuances for each material is referred to Chung *et al*. (2002, 2003).

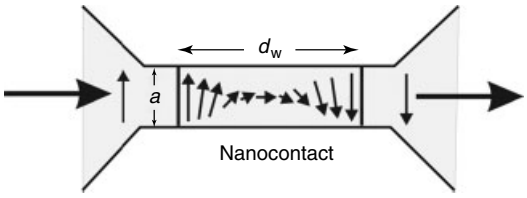

Figure 19. The nanocontact between two ferromagnetic wires is shown schematically. The domain wall in the nanocontact has a lateral thickness of d_w and a width corresponding to that of the nanochannel, a. The current through the nanochannel is shown by the horizontal arrows. The magnetization vector rotates across the domain between the initial and final magnetization directions in the two wires.

4 CONCLUDING REMARKS

In summary, geometry plays an important role in determining the magnetotransport properties of EMR and BMR structures on both the macroscale (EMR) and on the nanoscale (EMR and BMR). EMR derives from the orbital motion of carriers in nonmagnetic materials while BMR results from the interactions of spins with domains in magnetic materials. EMR has been observed in both InSb and InAs narrow-gap semiconductors with a variety of structures and at a range of temperatures down to that of liquid helium. The narrow-gap semiconductors are choice materials for EMR devices because of their concomitantly high carrier mobility. Following the discovery of EMR it has been realized that it is but one example of a broad class of geometry-driven interfacial 'EXX' effects in MSHs where proof of principal has been demonstrated for XX = piezoconductance (PC) (Rowe, Hines and Solin, 2003), optoconductance (OC) (Wieland *et al*., 2006) and electroconductance (EC) (Wang, Wieland and Solin, 2007).

The initial controversy about BMR, and the uncertainties about the governing mechanisms (e.g., as to whether it is due to magnetostriction), have now been resolved (Sullivan *et al*., 2005) by more careful experiments from several research groups. It is evident that the phenomenon of BMR is dependent heavily on the geometry of the nanocontact. A large value of BMR depends on the two key parameters, a large value for the ratio of the density of states at the Fermi level associated with the electron distributions with the two electron spin polarizations, and on a small value for the ratio of the DW thickness d_w to the mean free path ℓ for spin reversal. In ballistic nanocontacts, the length ℓ is essentially the length of the nanochannel. With the anticipated technological applications, research on BMR in novel materials, the dependence on quantum effects, and its geometric enhancement will continue to be a fascinating aspect of research on the physical behavior of materials at the nanoscale.

Both EMR and BMR portend significant potential for impact on magnetic sensor technology, particularly in the area of ultrahigh-density magnetic recording. Nevertheless, neither of these new phenomena have, to date, had any 'kinetic' impact on technology as is usually the case for discoveries that represent a new paradigm competing with an established conventional technology, for example, GMR

and TMR. Accordingly, it will be very interesting to monitor the development of EMR and BMR over the next few years to see if their promise as novel magnetic sensors is actually fulfilled.

ACKNOWLEDGMENTS

Our work on the EMR and FEM described in this review has benefited from the stimulating interactions and major contributions of our collaborators and students. Included among the former group are D.R. Hines, T. Thio, J. Bennett, the late R.A. Stradling, J. Heremans, J.S. Tsai, Y. Pashkin, M.B. Santos, A.C.H. Rowe, M. Lee, N. Wingreen, P.A. Wolff, S. Schwed, T. Zhou, S.J. Chung, and N. Goel. In the latter group, we include A. Girgis, J. Moussa, K. Weiland, Y. Shao and Y. Wang. Naturally, the responsibility for any errors or omissions in the content of this article rests solely with the authors. We gratefully acknowledge the support of the US National Science Foundation (NSF) under grant ECS-0329347. SAS also acknowledges support of the US National Institute of Health (NIH) under grant 1U54CA11934201 and of the UK Engineering and Physical Sciences Research Council (EPSRC) under grant EP/C511816/1 (L.F. Cohen, PI).

APPENDIX

A LANDAUER FORMULA FOR QUANTIZED CONDUCTANCE

In this Appendix, it is useful to provide a brief derivation of the Landauer formula (Landauer, 1957; Buttiker, Imry, Landauer, and Pinhas 1985) for quantized conductance in ballistic electron transport through very narrow structures since it provides a frame of reference for the discussion on BMR. Electrons in the devices of dimensions ≈50 nm or less, so-called mesoscopic devices, start behaving more like waves than particles. With the mean free path becoming comparable to the dimensions of the electronic device, an electron is transmitted through the device ballistically with no scattering. The electron waves will display phase coherence, however, and undergo quantum interference effects as defined by the *geometry* of the mesoscopic device. These features of electron transport change the usual macroscopic nature of resistance, leading to a quantization of resistance. We give a qualitative derivation of the Landauer relation defining the quantized conductance in terms of the transmission coefficient of electron waves through the device. The electron waves are guided through the device in a manner similar to optical waveguides.

It is useful to visualize the structure used in the original experiments. A two-dimensional electron gas (2DEG) created at the interface between a thin layer of GaAs and n-doped AlGaAs was used. By placing contacts for gates on the surface of the GaAs layer, as in Figure 20, it is possible to measure the electrical resistance, R, of the 2DEG in its flow through the split-gate channel. When the channel is constricted by the application of a gate voltage, the resistance of the device is essentially the resistance of the channel. In the absence of any scattering one might anticipate that the carriers will go through ballistically with no resistance at all; however, this is not so, and the resistance of the device remains finite.

One of the results of Landauer's theory (Landauer, 1957; Buttiker, Imry, Landauer, and Pinhas 1985) of conductance in mesoscopic devices is that the device may be thought of as two-contact reservoirs of carriers maintained at constant electro-chemical potentials μ_1 and μ_2 with the 'quantum device' in between, as shown in Figure 20. The current I through the device is proportional to $\mu_1 - \mu_2$, and its conductance $G = 1/R$ is given by

$$G = \frac{2e^2}{\hbar} \sum_{\mu\nu} T_{\mu\nu} \tag{A1}$$

The device is treated as a waveguide with input and output modes labeled by μ and ν with the transmission coefficients $T_{\mu\nu}$ at the Fermi energy being labeled accordingly.

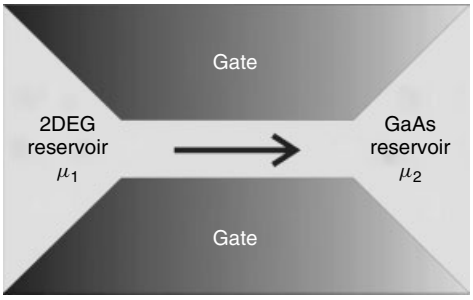

Figure 20. A narrow channel created by a split-gate structure in a 2DEG under bias. The electrons flow from the reservoir with Fermi level μ_1 to the reservoir with Fermi level μ_2 through the narrow channel. The arrow indicates the direction of the electron flow under bias.

Experiments performed independently by Wharam *et al*. (1988) and by van Wees *et al*. (1988, 1991) confirmed this remarkable quantization of resistance. Here we follow the arguments given by Wharam *et al*. (1988) and by Sharvin (1965a,b) to derive this result. The waveguide of Figure 17, which is an idealization of an actual experimental structure, has transverse modes, labeled by an index μ, having energy

$$E_y^{(\mu)} = \frac{\hbar^2 k_\mu^2}{2m^*} = \frac{\hbar^2}{2m^*} \frac{\pi^2 \mu^2}{L^2} \tag{A2}$$

Here L is the transverse width of the waveguide and m^* is the electron's effective mass in the medium. The current in a given subband μ associated with the energy of motion along the lateral direction of the waveguide is given by

$$I_\mu = n_\mu e \, \delta v_\mu \tag{A3}$$

where n_μ is *half* of the number of carriers per unit length in the subband, since only half the electrons have wave vectors in the $+x$ direction. In the preceding equation, e is the electron charge and δv_μ is the increase in velocity. The number of carriers n_μ contributing to the current, including a spin degeneracy factor of 2, is

$$n_\mu = \frac{2}{2\pi} \int_0^{k_{\max}} \mathrm{d}k = \frac{2m^* \, v_\mathrm{F}}{2\pi\hbar} \tag{A4}$$

The change in kinetic energy is given in terms of the applied voltage as

$$eV = \mu_1 - \mu_2 = \frac{1}{2} m^* \, (v_\mathrm{F} + \delta v_{\mu\mathrm{F}})^2 - \frac{1}{2} m^* \, v_\mathrm{F}^2 \tag{A5}$$

so that for $\delta v_{\mu\mathrm{F}} \ll v_F$ we have

$$\delta v_{\mu\mathrm{F}} = \frac{eV}{m^* \, v_{\mu\mathrm{F}}} \tag{A6}$$

Now the current in the channel is given by

$$I = \frac{2e^2}{2\pi\hbar}V \tag{A7}$$

and the conductance corresponding to carriers in one subband is

$$G_0 = \frac{2e^2}{h} \tag{A8}$$

This conductance is dependent only on fundamental physical constants and is the same for any transmission mode. The resistance standard defined by this relation has the value: $R = 1/G_0 = 25,812.8056 \pm 0.0012\,\Omega$. For transmission in more than one transverse mode of the waveguide, we can estimate the total conductance assuming that the transport of carriers in the various modes is independent of each other. In this case, the double sum over incoming and outgoing modes reduces to just one and we have

$$G = \frac{2e^2}{h}N \tag{A9}$$

for N channels.

The preceding derivation leads to a resistance quantization essentially because there is a cancellation of the velocity dependence of the number density and the change in the velocity, in the expression for the current in one dimension. The resistance of the system may be thought of as arising from the contacts between the waveguide and the reservoirs at the two ends.

For more elaborate treatments for the calculation of the quantized resistance the reader is referred to the original articles of Landauer (1957), and Buttiker, Imry, Landauer, and Pinhas (1985) and the review articles by Beenakker and van Houten (1991) and van Houten, Beenakker and van Wees (1992) and by Imry (1986) A treatment using quantum kinetic equations is given by Mclennan, Lee and Datta (1991). A derivation using the usual Kubo formalism for linear response theory is also available (Baranger and Stone, 1989).

Similar considerations apply for the BMR in point contacts, except that the spin polarization of the electrons has to be taken into account. The transport through the point contact from one ferromagnetic lead into another depends on the spin polarizations of the initial and the final leads. The factor of 2 arising from spin in equation (A9) is then dropped and the conductances in the parallel and antiparallel spin polarizations in the leads are denoted by $G_{\uparrow\uparrow}$ and $G_{\uparrow\downarrow}$, respectively. These are used in the definition of the BMR in the earlier sections.
